by a 6-week double-blind, placebo-controlled five-center trial by Lineberry et al. (1990), which supported the conclusion that bupropion IR 300 mg/day was more efficacious than placebo in treating major depressive disorder. In evaluations against TCAs such as doxepin, amitriptyline, and imipramine in several clinical trials, bupropion was demonstrated to be equally efficacious (Branconnier et al. 1983; Feighner et al. 1986; Mendels et al. 1983). These studies also noted the more benign side-effect profile and improved tolerability of bupropion IR in comparison with TCAs. In 1991, Feighner et al. examined the efficacy of bupropion and fluoxetine in treating depressed outpatients and found it to be comparable. In addition, similar effectiveness in treating depression was also found between trazodone and bupropion IR (Weisler et al. 1994).

After the development of bupropion SR, many studies followed comparing bupropion SR with SSRIs, including fluoxetine, sertraline, and paroxetine. In most studies, the effective daily dosage of bupropion SR was between 300 mg and 400 mg. All studies demonstrated that bupropion's effectiveness in treating symptoms of depression was equal to that of SSRIs (Coleman et al. 1999, 2001; Croft et al. 1999; Kavoussi et al. 1997; Weihs et al. 2000). In 2005, a meta-analysis of remission rates using all existing bupropion SR versus SSRI comparative trials was conducted by Thase et al. (2005). This analysis also found that remission rates with these two types of antidepressants were essentially the same. Although bupropion SR and SSRIs both were generally well tolerated, bupropion SR treatment was associated with less sexual dysfunction (Thase et al. 2005). Bupropion SR has also been shown to prevent relapse of depressive symptoms when given up to 1 year (Weihs et al. 2002).

Like bupropion IR and bupropion SR, the third and most recently released formulation of this NDRI, bupropion XL, has also been studied in regard to its effectiveness in treating depressive symptoms. In two 8-week placebo-controlled comparative trials with bupropion XL and escitalopram, pooled analysis confirmed equivalent efficacy of the two agents based on mean change in Hamilton Rating Scale for Depression (Ham-D; Hamilton 1960) score. Both antidepressants produced remission rates greater than the rate with placebo alone (Clayton et al. 2006). Other studies comparing bupropion XL with the serotonin and norepinephrine reuptake inhibitor (SNRI) venlafaxine XR demonstrated clinical equivalence for the two drugs in the treatment of depression. However, a study that used higher dosages of bupropion XL (300–450 mg/day) found statistically significantly higher remission rates for bupropion XL relative to venlafaxine XR (Thase et al. 2006).

It is also important to note that for patients who are unable to tolerate or fail to respond to SSRIs, bupropion may be added. Studies have shown bupropion to be efficacious for treatment of major depressive disorder not only as monotherapy but also as an augmenting agent with SSRIs or SNRIs (Bodkin et al. 1997; DeBattista et al. 2003; Fava et al. 2003; Ferguson et al. 1994; Lam et al. 2004; Rush et al. 2006; Spier 1998; Stern et al. 1983; Trivedi et al. 2006).

Depression in the elderly

Depression in the elderly is often underdiagnosed and may go untreated. Elderly patients with depression frequently report less specific symptoms, such as insomnia, anorexia, and low energy, instead of admitting to depressed mood (Birrer and Vemuri 2004). Bupropion has been found to be an effective antidepressant in elderly patients (Birrer and Vemuri 2004; Branconnier et al. 1983; Weihs et al. 2000). An early study concluded that bupropion had therapeutic advantages over TCAs because it alleviated depressive symptoms without producing sedation or anticholinergic side effects, such as dry mouth, constipation, or confusion (Branconnier et al. 1983). A later study comparing bupropion SR and paroxetine noted that although both agents were effective in treating depression, bupropion SR had a more favorable side-effect profile (Weihs et al. 2000). Like bupropion SR, bupropion XL has proven efficacious for treatment of depression in the elderly (Clayton 2007). A recent study examining gender- and age-related differences in treatment of depressive symptoms, anxious and somatic symptoms, and insomnia found SSRIs and bupropion to be equally effective (Papakostas et al. 2007).

Depression with decreased energy, interest, and pleasure

Bupropion XL has been studied specifically in patients with a retarded–anergic profile. Jefferson et al. (2006) showed that bupropion XL was more effective than placebo in treatment of patients with decreased energy, pleasure, and interest. This is the first study to look at those parameters exclusively. The unique NDRI mechanism of action of bupropion may play a role in its effectiveness in treating these symptoms (Jefferson et al. 2006).

Anxiety symptoms in depression

Studies have demonstrated the effectiveness of bupropion dosages of 300–400 mg/day in reducing symptoms of anxiety (Fabre et al. 1983). Moreover, bupropion and SSRIs appear to be equally effective in this realm (Feighner et al. 1991; Weihs et al. 2000). In 2001, Trivedi et al. published results of a study examining the effects of bupropion SR versus sertraline on anxiety in depressed patients. This was a retrospective, pooled analysis of two 8-week double-blind, placebo-controlled trials that used the Hamilton Anxiety Scale (Ham-A) and the 21-item Hamilton Rating Scale for Depression (Ham-D-21) to measure symptoms. Results revealed that both bupropion SR and sertraline were superior to placebo in allaying depressive symptoms; however, treatment of anxious symptoms did not significantly differ from placebo for either active medication. The study concluded that bupropion and SSRIs were comparable in their antidepressant and anxiolytic effects in patients with major depressive disorder. Neither was favored for more specific management of anxiety (Trivedi et al. 2001). A more recent meta-analysis comparing efficacy of bupropion and selective serotonin reuptake inhibitors for treatment of anxious symptoms in major depressive disorder came to a similar conclusion. The study found that both classes of medication led to a similar degree of improvement in anxiety symptoms, with no significant difference in the severity of residual anxiety symptoms (Papakostas et al. 2008).

Bipolar depression

A small number of studies have demonstrated the advantages of bupropion in the treatment of depression in bipolar disorder (Haykal and Akiskal 1990; Shopsin 1983; Wright et al. 1985). Although these investigations yielded positive results, they were limited by small numbers of subjects and were uncontrolled. A study by Sachs et al. (1994) comparing bupropion and desipramine in the treatment of bipolar depression suggested that bupropion may have a lower rate of precipitation of mania. Another study comparing the effect of bupropion SR versus topiramate, as an add-on agent for bipolar depression in patients already taking lithium or valproate, demonstrated no difference in response. Regarding change from baseline, a significant reduction in depressive symptoms occurred with both medications. This study reported no cases of affective switching in either arm (McIntyre et al. 2002).

Seasonal Affective Disorder

Bupropion XL is the first, and currently the only, medication to have a labeled indication for the preventive treatment of SAD. A study published in 1992 initially suggested bupropion's efficacy as treatment for SAD (Dilsaver et al. 1992). In 2005, Modell et al. published results of three prospective randomized, placebo-controlled prevention trials involving 1,042 outpatients with a diagnosis of SAD. Patients received 150–300 mg/day of bupropion XL or placebo in autumn while they were still well. Bupropion XL reduced the frequency of emergence of SAD by 44% and protected against the recurrence of seasonal major depressive episodes. Furthermore, there was no noticeable increase in major depressive episodes following discontinuation of bupropion in the springtime (Modell et al. 2005).

Smoking Cessation

The smoking cessation activity of bupropion was first noted after researchers observed unplanned suspension of smoking in depressed subjects who were being treated with bupropion (Hudziak and

Rettew 2004). In 1997, Hurt et al. published the results of a double-blind, placebo-controlled trial of bupropion SR therapy for smoking cessation. Six hundred and fifteen subjects received bupropion SR at dosages of 100, 150, or 300 mg/day for 7 weeks, with a target quit date of 1 week after beginning treatment. Brief counseling was also provided. Rates of smoking cessation at the end of 7 weeks were 29% for the 100-mg group, 39% for the 150-mg group, and 44% for the 300-mg group, versus 10% for placebo. At 1 year, rates for the three bupropion dosage groups were 20%, 23%, and 23%, respectively, compared with 12% for the placebo group. Cessation rates for the two higher dosages were significantly better than the rate for placebo. This trial concluded that bupropion SR is an effective agent for smoking cessation (Hurt et al. 1997).

A later placebo-controlled study compared bupropion SR alone, nicotine patch alone, bupropion SR plus nicotine patch, and placebo. At 1 year, rates of smoking cessation were significantly higher in both the bupropion monotherapy group and the bupropion plus nicotine patch group than in the placebo group or the nicotine patch monotherapy group (Jorenby et al. 1999). In 2004, Killen et al. published results of the first study in adolescent smokers. In that study, 211 adolescent smokers (ages 15–18 years) were randomly assigned to two groups. One group received the nicotine patch plus placebo, and the other received the nicotine patch plus bupropion SR 150 mg/day. Both groups also received relapse prevention skills training. Results did not show a significant treatment effect but did reveal an overall reduction in cigarette consumption per day and maintenance of this reduction over time (Killen et al. 2004).

Clinical trials have demonstrated that bupropion SR is effective in improving initial and long-term abstinence rates and may be helpful in preventing relapse. Hays et al. (2001) showed that subjects who had successfully stopped smoking for 7 weeks with bupropion treatment had a significant delay in smoking relapse with continued bupropion SR therapy compared with placebo. More recently, however, a trial looking specifically at extended treatment with bupropion SR for smoking cessation reported that bupropion SR did not surpass placebo (Killen et al. 2006). In the first study arm, 362 adult smokers received 11 weeks of open-label treatment consisting of bupropion SR, nicotine patch, and relapse prevention training. In the second arm of the study, subjects were randomly assigned to placebo or bupropion SR for 14 weeks of extended treatment. Whereas higher abstinence rates with bupropion SR than with placebo were found at week 25 (42% vs. 38%), abstinence rates were about the same at week 52 (33% vs. 34%). Another interesting finding this study uncovered was that men were more likely than women to abstain from smoking.

Although more work needs to be done in areas of relapse prevention and long-term abstinence, it is clear that bupropion SR is helpful in smoking cessation. Many of theses studies were instrumental in the approval of bupropion SR for smoking cessation. Recommended dosages are 150 mg/day for 3 days, with an increase to 150 mg two times a day for 7–12 weeks. The patient should set a quit date of 1–2 weeks after treatment has been initiated. In 2003, Ferry and Johnston published a 5-year review of efficacy and safety data for bupropion SR in smoking cessation since its approval in 1997 for that indication. A risk–benefit analysis assuming a 30% 1-year quit rate found that 19 lives were saved out of 10,000 subjects and that 86 of the cases of smoking-attributed morbidity were avoided compared with a 0.22% chance of experiencing an adverse effect from bupropion SR (Ferry and Johnston 2003).

Other Uses

Attention-Deficit/Hyperactivity Disorder

Currently there is no FDA indication for this use, but studies have demonstrated that bupropion may also be helpful is treating symptoms of ADHD in both children and adults. Clinical trials in children with ADHD have shown bupropion to be a safe and effective alternative for treatment of this disorder (Conners et al. 1996; Simeon et al. 1986). A comparison trial of bupropion and methylphenidate

demonstrated that both drugs were effective in the treatment of ADHD and had similar efficacy (Barrickman et al. 1995). Bupropion has also been studied in adults with ADHD and has demonstrated statistically significant symptom improvement in this population (Wilens et al. 2001). In a meta-analysis by Peterson et al. (2008), long-acting forms of bupropion appeared to exhibit similar clinical effectiveness compared with long-acting stimulants in adults. An open trial by Riggs et al. (1998) suggested that bupropion may also be useful for treatment of ADHD in adolescents with both conduct disorder and substance abuse (Riggs et al. 1998).

Currently, bupropion is thought of as a useful second-line agent in the treatment of ADHD and may be more favorable with comorbid conduct disorder or substance abuse (Riggs et al. 1998; Wilens et al. 2001). More studies are needed to further establish the efficacy of bupropion for use in this realm.

Obesity

One of the well-known characteristics of bupropion is that it is usually not associated with weight gain as are many other classes of antidepressants. Alternatively, mild weight loss has been noted in many clinical trials. To further investigate this observation, Gadde et al. (2001) conducted a randomized, placebo-controlled trial investigating the tolerability and efficacy of bupropion for weight loss in 50 obese women using bupropion (100–400 mg/day) versus placebo. All subjects kept a food journal and were placed on a 1,600 kcal/day diet. Results revealed bupropion to be more effective than placebo in achieving weight loss at 8 weeks. At 24 weeks, responders to bupropion had lost an average of 13% of their baseline body weight (Gadde et al. 2001). Following this initial study for bupropion and weight loss, two larger studies confirmed these results (Anderson et al. 2002; Jain et al. 2002). A more recent randomized, open-label study found that combination treatment with zonisamide and bupropion resulted in more weight loss than treatment with zonisamide alone. Eighteen obese women were randomly assigned to receive either combination therapy or zonisamide monotherapy. For those who completed the study, women in the combination group lost an average of 8.1 kg, versus an average of 3.0 kg for women in the monotherapy group (Gadde et al. 2007). Although bupropion is not FDA approved for weight reduction, it may mitigate weight gain in patients being treated for depression.

Sexual Dysfunction

Studies by Segraves et al. (2001) demonstrated that bupropion may be helpful in treatment of hypoactive sexual desire disorder (HSDD). More recently, a double-blind, placebo-controlled trial supported this finding and also revealed increases in sexual arousal, orgasm completion, and sexual satisfaction in women with HSDD receiving bupropion (Segraves et al. 2004). Another study of bupropion SR treatment of patients with SSRI-induced sexual dysfunction found that bupropion improved desire to engage in sexual activity and increased frequency of engaging in sexual activity (Clayton et al. 2004). Further studies have also demonstrated that bupropion may be helpful for treatment of sexual disorders in both men and women (Modell et al. 2000).

SIDE EFFECTS AND TOXICOLOGY

Thousands of clinical trials and millions of patient exposures reveal bupropion to be a safe and generally well tolerated medication across populations. Because of its unique mechanism of action and structure, its reported side effects are somewhat different than with other antidepressants.

In a series of large randomized, placebo-controlled multicenter trials evaluating the safety of bupropion SR in the treatment of depressed outpatients, Settle et al. (1999) found that the most commonly reported adverse events (occurring in >5% of subjects) were headache, dry mouth, nausea, insomnia, constipation, and dizziness. Only three of these—dry mouth, nausea, and insomnia—occurred at higher rates in patients taking bupropion SR than in those receiving placebo. The rate of discontinuation due to adverse events was low: 7% for bupropion SR, compared with 4% for placebo.

Rash, nausea, agitation, and migraine were the most common adverse effects leading to discontinuation (Settle et al. 1999). Similarly favorable safety and tolerability findings were reported for continuation-phase bupropion SR treatment in a longer-term (up to 44 weeks) relapse prevention trial (Weihs et al. 2002).

Adverse events associated with bupropion XL are presented in Table 20–1. This table is based on combined results from four different studies previously discussed: the two escitalopram studies (Clayton et al. 2006); the venlafaxine XR study (Thase et al. 2006); and the reduced energy, pleasure, and interest study (Jefferson et al. 2006). These data indicate that the most common side effects of bupropion XL are similar to those of other formulations. Fatigue and somnolence were associated more with escitalopram, whereas bupropion XL caused more dry mouth. Compared with bupropion XL, venlafaxine XR was found to be associated with more dry mouth, nausea, diarrhea, somnolence, sedation, and yawning. These data indicate that bupropion XL does not appear to cause somnolence (Clayton et al. 2006).

A review by Fava et al. (2005) presented similar conclusions, supporting the evidence that bupropion

causes much less somnolence than SSRIs. Moreover, insomnia, a known adverse effect of bupropion, occurs at rates similar to those seen with SSRIs (Fava et al. 2005).

Other important adverse events that have been reported with bupropion may include seizure, allergic reaction, or vital sign changes. These are less common but could possibly be more harmful. Allergic reactions, including rash, arthralgias, fever, and serum sickness–like reactions, have all been reported (Kanani et al: 2000; McCollom et al. 2000). In light of these data, it is important to fully evaluate any reports of hypersensitivity when administering bupropion.

Screening for a history of seizure disorder or other organic brain disease should be performed before commencing a trial of bupropion. Seizure has been reported at a rate of 0.1% at dosages up to 300 mg/day with bupropion SR, with a dose-related effect (Dunner et al. 1998). This rate is similar to that of other newer antidepressants, such as SSRIs and mirtazapine, but lower than the rate associated with therapeutic doses of TCAs (Montgomery 2005).

Although cases of spontaneous hypertension with bupropion therapy have been reported, clinical trials have also shown minimal changes in heart rate and blood pressure (Settle et al. 1999). In a smoking cessation study, patients receiving combination treatment with both bupropion SR and a nicotine patch had a higher incidence of new or worsening hypertension compared with patients receiving either treatment alone or placebo (Jorenby et al. 1999). Thase et al. (2008) conducted a dose–response study to evaluate the potential of bupropion to elevate blood pressure. Bupropion SR dosages of 150–400 mg/day were administered to 296 nondepressed volunteers with mild hypertension. Results revealed that bupropion SR did not separate from placebo on blood pressure changes. However, clinicians should be aware that elevated blood pressure is a possibility with bupropion therapy and should monitor patients accordingly.

Many agents used to treat depression have been associated with weight gain. This effect is thought to be due to an affinity for the H_1 histamine receptor, which is not a factor with bupropion. In fact, mild weight loss over time, instead of weight gain, has been reported with bupropion treatment (Harto-Truax et al. 1983). Studies have shown bupropion XL to be associated with a loss of 0.1–1.1 kg in the short term, compared with placebo, which was linked with a small gain of 0.1–0.8 kg (Jefferson et al. 2006; Modell et al. 2005; Thase et al. 2006). In a longer-term depression relapse prevention study, Croft et al. (2002) observed that patients with a higher body mass index at baseline experienced greater weight loss with bupropion XL.

Another difference in bupropion's tolerability compared with other antidepressants is the lower incidence of sexual dysfunction. A comparative meta-analysis of bupropion SR and SSRIs concluded that bupropion SR therapy resulted in lower rates of sexual dysfunction than did SSRI therapy (Thase et al. 2005). Orgasmic dysfunction, sexual arousal disorder, and sexual desire disorder were all less frequent with bupropion SR. Notably, the risk of sexual dysfunction with bupropion SR in this study was comparable to that with placebo. Data from two comparative studies also confirm lower rates of sexual dysfunction with bupropion SR than with the SSRI escitalopram (Clayton et al. 2006). Furthermore, a large study published in 2002 examining the prevalence of sexual dysfunction among outpatients on monotherapy with newer antidepressants found that the odds of developing sexual dysfunction were four to six times greater with SSRIs or venlafaxine XR than with bupropion SR (Clayton et al. 2002). As a result of these data, studies have examined bupropion as an antidote for SSRI-induced sexual dysfunction. A placebo-controlled comparative trial of bupropion SR treatment in 42 patients with SSRI-induced sexual dysfunction concluded that bupropion SR improved both desire to engage in sexual activity and frequency of engaging in sexual activity relative to placebo (Clayton et al. 2004). Use of bupropion for the treatment of SSRI-induced sexual dysfunction has not yet been approved by the FDA. Further investigation is needed.

Overall, at approved dosages, bupropion is a safe medication for depression in most populations and

has an excellent tolerability profile. Although safe in general, bupropion can be fatal with high blood levels. Serious medical consequences such as hypertension, acidosis, sinus tachycardia, seizures, cardiotoxicity with QRS widening, and even death have all been reported with overdoses of bupropion (Bhattacharjee et al. 2001; Curry et al. 2005; Shrier et al. 2000).

On initiation of bupropion therapy, it is usually not necessary to obtain routine laboratory evaluations, although cases of elevated serum transaminase (Oslin and Duffy 1993) and rare cases of hepatitis (Hu et al. 2000) have been reported. Other unexpected changes in laboratory values have also occurred with bupropion therapy and include false-positive urine amphetamine screening results (Weintraub and Linder 2000).

Unfortunately, there is little evidence about the safety of bupropion in pregnancy. In a recent study by Cole et al. (2007), bupropion exposure in the first trimester was not associated with teratogenic effects.

DRUG–DRUG INTERACTIONS

As discussed earlier, the major pathway for metabolism of bupropion to its primary metabolite, hydroxybupropion, occurs through the cytochrome P450 system in the liver. The main enzyme responsible for this metabolism is CYP2B6. Competitive inhibition of metabolism could occur with other drugs processed by this enzyme, such as paroxetine, sertraline, diazepam, clonazepam, clopidogrel, ritonavir, and efavirenz (Hesse et al. 2000; Jefferson et al. 2005). A study examining the effects of concurrent use of lopinavir/ritonavir on bupropion pharmacokinetics in 12 healthy subjects found that maximum plasma concentrations of bupropion and hydroxybupropion decreased by 57% and 31%, respectively (Hogeland et al. 2007).

Bupropion and hydroxybupropion are also inhibitors of CYP2D6, an essential enzyme that plays a role in the metabolism of several classes of medications, including antidepressants, β-blockers, and antiarrhythmic agents (Wilkinson 2005). Studies of the effects of bupropion on CYP2D6 activity are limited (Jefferson et al. 2005). Coadministration of bupropion SR with desipramine, a drug extensively metabolized by CYP2D6, results in decreased clearance of desipramine and increased maximum plasma concentrations and area under the curve of desipramine (Jefferson et al. 2005). Similarly, in an 8-week open-label study of bupropion SR coadministered with venlafaxine, paroxetine, or fluoxetine, venlafaxine metabolism was inhibited and higher concentrations of venlafaxine were found. No significant interaction effects were seen for paroxetine or fluoxetine (Kennedy et al. 2002). Other agents known to induce various metabolic pathways have also been shown to affect the metabolism of bupropion. Carbamazepine, which induces CYP2B6, 3A4, and 1A2 activity, has been shown to decrease bupropion concentrations but increase hydroxybupropion concentrations.

Bupropion should also be used with caution if coadministered with other agents that can lower the seizure threshold, such as tramadol, other antidepressants, or antipychotics (Delanty et al. 1998; Gardner et al. 2000). It should also be used with caution in patients who abuse alcohol, as this population may have increased risk for seizures (Dunner et al. 1998). In addition, because bupropion increases DA reuptake, additive effects with other dopaminergic agents (e.g., levodopa) have been observed (Goetz et al. 1984).

CONCLUSION

Bupropion is unique in that it works as a DA and NE reuptake inhibitor and acts as an antagonist of nACh receptors. Unlike other newer agents, it has very little serotonergic activity and therefore produces a different side-effect profile. Bupropion may be the antidepressant of choice for patients who cannot tolerate or do not respond to SSRIs. While currently indicated for major depressive disorder, for tobacco dependence, and for prevention of SAD, bupropion has also proven useful in many other circumstances, such as child and adult ADHD, obesity, and sexual disorders. For more specific treatment of depression with decreased energy and interest, for depression with concomitant

anxiety, and for bipolar depression, bupropion may be beneficial. Bupropion may also be used to augment other antidepressants in the treatment of major depressive disorder and to reverse SSRI-induced side effects. Greater tolerability, including low risk of weight gain, less sedation, and fewer sexual side effects, adds to its value as an effective antidepressant.

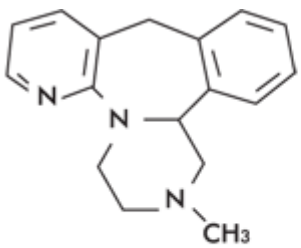
Chapter 21. Mirtazapine



HISTORY AND DISCOVERY

Mirtazapine, originally known as ORG 3770, was first synthesized by the Department of Medicinal Chemistry of NV Organon in the Netherlands (Kaspersen et al. 1989). First approved for use in major depression in the Netherlands in 1994, mirtazapine was introduced in the United States in 1996. The new drug application consisted of 47 Phase II/III clinical trials involving 2,796 mirtazapine-treated patients, 605 placebo-treated patients, and 1,161 active-control patients (Fawcett and Barkin 1998b).

STRUCTURE–ACTIVITY RELATIONS

Mirtazapine is a member of the piperazinoazepines, a class of chemical compounds that is unrelated to any other class used in the treatment of psychiatric conditions (Maris et al. 1999) (Figure 21–1). Mirtazapine is also known by its chemical name, 1,2,3,4,10,14b-hexahydro-2-methylpyrazino[2,1-a]pyridol[2,3-c]benzazepine (Dahl et al. 1997; Dodd et al. 2000).

PHARMACOLOGICAL PROFILE

Mirtazapine is described as a noradrenergic and specific serotonergic antidepressant (NaSSA) (Holm and Markham 1999; Kent 2000; Nutt 1998). It is a potent serotonin$_2$ (5-HT$_2$), serotonin$_3$ (5-HT$_3$), and central α_2-adrenergic receptor antagonist (De Boer 1996; De Boer et al. 1995; Kooyman et al. 1994). Antagonism of 5-HT$_2$ and 5-HT$_3$ receptors results in an increase in serotonin$_{1A}$ (5-HT$_{1A}$) receptor–mediated transmission and, thus, a more specific effect on serotonergic transmission, relative to the selective serotonin reuptake inhibitor (SSRI) class of antidepressants (Bengtsson et al. 2000; Berendsen and Broekkamp 1997; Kent 2000). In addition, because α_2-adrenergic receptors normally act to inhibit transmission at serotonergic and noradrenergic axon terminals, mirtazapine acts to increase the release of both serotonin (5-HT) and norepinephrine (NE) via blockade of central α_2 receptors (Numazawa et al. 1995).

Mirtazapine has no significant affinity for dopamine (DA) receptors, low affinity for muscarinic cholinergic receptors (De Boer 1996), and high affinity for histamine$_1$ (H$_1$) receptors (De Boer 1996). Mirtazapine appears to have no effect on 5-HT and DA reuptake and only a minimal effect on NE reuptake (De Boer 1996; Kent 2000). The drug appears to significantly reduce cortisol levels (Laakmann et al. 2004; Schmid et al. 2006).

PHARMACOKINETICS AND DISPOSITION

Absorption

Mirtazapine is well absorbed from the gastrointestinal tract, and bioavailability does not appear to be affected by the presence of food in the stomach (Fawcett and Barkin 1998b). An oral rapidly disintegrating tablet has been well studied and available for several years (Benkert et al. 2006).

Distribution

Mirtazapine appears to be 85% bound to plasma proteins (Fawcett and Barkin 1998b).

Metabolism

Mirtazapine is primarily metabolized by the liver via demethylation and hydroxylation, followed by glucuronide conjugation (Fawcett and Barkin 1998b; Remeron package insert 2002). Its major metabolite, desmethylmirtazapine, is weakly active but present in lower serum concentrations than is the parent compound (Fawcett and Barkin 1998b; Kent 2000). Mirtazapine lacks both autoinduction and autoinhibition of hepatic cytochrome P450 (CYP) enzymes (Fawcett and Barkin 1998b). Although in vitro studies do not demonstrate inhibitory effect, mirtazapine is a substrate for CYP1A2, 2D6, and 3A4 (Fawcett and Barkin 1998b; Remeron package insert 2002). Mirtazapine is a mild competitive inhibitor of CYP2D6 (Barkin et al. 2000; Fawcett and Barkin 1998b).

Elimination

Mirtazapine and its metabolites are eliminated primarily in the urine (up to 75%) and feces (up to 15%) (Fawcett and Barkin 1998b). The elimination half-life of mirtazapine is 20–40 hours (Fawcett and Barkin 1998b; Remeron package insert 2002; Stimmel et al. 1997). Of note, the clearance of mirtazapine may be affected by hepatic or renal impairment (Fawcett and Barkin 1998b). The elimination half-life may increase by 30%–40% in patients with hepatic impairment (Fawcett and Barkin 1998b; Kent 2000). In patients with moderate to severe renal impairment, the clearance of mirtazapine may be decreased by 30%–50% (Fawcett and Barkin 1998b; Kent 2000; Remeron package insert 2002).

INDICATIONS AND EFFICACY

Major Depression

Pooled data from the 6-week U.S. clinical trials that were part of the new drug application showed that approximately 50% of mirtazapine-treated patients and 20% of placebo-controlled patients achieved at least a 50% improvement in scores on the Hamilton Rating Scale for Depression (Ham-D) (Fawcett and Barkin 1998b).

In a randomized, double-blind, placebo-controlled study of 90 patients with major depression, mirtazapine treatment resulted in clinically significant reductions in Ham-D scores by study endpoint at 6 weeks, although improvement was noted as early as the first week (Claghorn and Lesem 1995).

A meta-analysis of four randomized, double-blind 6-week studies demonstrated mirtazapine to be as effective as amitriptyline in the treatment of major depression, but with significantly fewer anticholinergic, serotonergic, and cardiovascular adverse effects (Stahl et al. 1997).

In a multicenter randomized, double-blind study comparing mirtazapine and fluoxetine, both medications were found to be well tolerated in the treatment of major depression, although the former was noted to demonstrate a significantly greater improvement in Ham-D scores, beginning in the third week of treatment (Wheatley et al. 1998).

When mirtazapine was compared with paroxetine in a randomized, double-blind study of 275 patients with major depression, the two drugs were found to be, overall, equally well tolerated and efficacious,

but mirtazapine was noted to result in significantly lower Ham-D and Hamilton Anxiety Scale (Ham-A) scores at week 1 (Benkert et al. 2000).

Similarly, when compared with citalopram in a multicenter randomized, double-blind, 8-week study of 270 patients with major depression, mirtazapine was equally well tolerated and efficacious at study endpoint, but significantly more effective on Ham-A, Montgomery-Åsberg Depression Rating Scale (MADRS), and Clinical Global Impression (CGI) Scale scores by week 2 (Leinonen et al. 1999).

Of interest, in a multicenter randomized, double-blind 8-week study comparing two antidepressants with both serotonergic and noradrenergic activity, mirtazapine was found to be equal in efficacy to venlafaxine in the treatment of major depression with melancholic features, although it demonstrated a trend, which was not statistically significant, toward a higher percentage of responders and remitters (Guelfi et al. 2001).

The sleep effects of mirtazapine in major depression were recently reported by Steiger's group (Schmid et al. 2006). Mirtazapine improved sleep continuity by day 2 of therapy, and the effect was sustained for at least 4 weeks. At day 28, significant increases in slow-wave and low-delta sleep were also observed.

Treatment Failure With a Selective Serotonin Reuptake Inhibitor

In an 8-week open-label study of 103 outpatients with DSM-IV (American Psychiatric Association 1994) major depressive disorder complicated by failure to respond to (or intolerance of) treatment with fluoxetine, paroxetine, or sertraline, approximately one-half of the outpatients demonstrated a 50% reduction in the 17-item Ham-D (Ham-D-17) score when switched to treatment with mirtazapine (Fava et al. 2001).

In a 4-week study of patients with persistent major depression, despite adequate antidepressant monotherapy, augmentation with mirtazapine resulted in a 45% remission rate, compared with a 13% remission rate among patients receiving placebo augmentation (Carpenter et al. 2002). Of note, in this latter study, there were no significant differences in terms of side effects between patients treated with mirtazapine augmentation and patients receiving placebo augmentation (Carpenter et al. 2002).

In level 3 of the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial, mirtazapine was compared with nortriptyline in patients who had failed to respond to two previous consecutive trials with antidepressants (Fava et al. 2006). Level 1 of STAR*D employed citalopram; level 2 employed a switch to another drug or augmentation. Nortriptyline produced higher remission rates than did mirtazapine (19.8% vs. 12.3%); however, the difference was not statistically significant.

Patients With Depression and Sexual Dysfunction

In an open-label study of 103 patients with depression treated with mirtazapine, 54% of patients who had reported poor or very poor sexual functioning during prior treatment with an SSRI described an improvement in sexual functioning by study endpoint (Fava et al. 2001).

Similarly, Gelenberg et al. (2000) reported 58% of patients with prior SSRI-induced sexual dysfunction had a return of normal sexual functioning when they switched to treatment with mirtazapine.

In contrast, augmentation with mirtazapine was no more effective than placebo augmentation in reversing SSRI-associated sexual side effects in patients with fluoxetine-associated sexual dysfunction (Michelson et al. 2002).

Depression in Elderly Patients

In a study of 150 outpatients (ages between 55 and 80 years) with moderate to severe depression, mirtazapine was found to be effective, safe, and well tolerated (Halikas 1995). In this 6-week trial,

50% of the mirtazapine-treated patients and 35% of the placebo-treated patients demonstrated at least a 50% reduction in Ham-D score (Halikas 1995). In another blinded study, mirtazapine was significantly more effective than paroxetine at weeks 1, 2, 3, and 6, but not at week 8, in subjects older than 65 years (Schatzberg et al. 2002). Differences were observed primarily on measures of anxiety and sleep. Apolipoprotein epsilon 4 (*ApoE*-ε4) carrier status predicted a positive response to mirtazapine (Murphy et al. 2003).

An oral disintegrating tablet has been studied in the elderly and appears to be well tolerated (Nelson et al. 2007; Varia et al. 2007).

Patients With Comorbid and Primary Symptoms of Anxiety

Meta-analyses of placebo-controlled studies of patients with depression and associated symptoms of anxiety have demonstrated that mirtazapine-treated patients exhibit significantly greater improvement in symptoms of anxiety (Fawcett and Barkin 1998a; Nutt 1998), beginning as early as the first week of treatment (Fawcett and Barkin 1998a).

In an 8-week open-label study of 10 patients with major depressive disorder and comorbid generalized anxiety disorder, mirtazapine treatment resulted in significant decreases in Ham-D and Ham-A scores, with improvement beginning as early as the first week of treatment (Goodnick et al. 1999).

Dysthymia

In a 10-week open-label trial of the use of mirtazapine in 15 patients with dysthymic disorder, 8 patients demonstrated at least a 40% reduction in Ham-D scores, and 4 of these 8 patients exhibited a remission of symptoms by study endpoint (Dunner et al. 1999).

Posttraumatic Stress Disorder

In an 8-week open-label study of six patients with severe chronic posttraumatic stress disorder (PTSD), mirtazapine treatment resulted in one-half of the patients demonstrating at least a 50% reduction in CGI score and significant reductions on scales of PTSD severity (Connor et al. 1999).

In a 6-week double-blind comparison study, mirtazapine was compared with sertraline in Korean veterans with PTSD (Chung et al. 2004). At study endpoint, mirtazapine was statistically significantly superior to sertraline on several measures (e.g., Clinician-Administered PTSD Scale—Part 2 [CAPS-2]). Efficacy was apparently maintained to 24 weeks (Kim et al. 2005).

Social Phobia

Mirtazapine was compared with placebo in a 10-week double-blind comparison study in 66 women with social phobia. Mirtazapine appeared to separate from placebo on several primary measures of social phobia symptoms (Muehlbacher et al. 2005).

Generalized Anxiety Disorder

In an open-label trial of mirtazapine treatment in 44 adult patients with generalized anxiety disorder, response criteria were achieved in 80% of patients (Gambi et al. 2005). Controlled trial data are not available.

Obsessive-Compulsive Disorder

Koran et al. (2005) reported on a two-phase study (a 12-week open-label phase followed by an 8-week double-blind discontinuation phase) of mirtazapine (maximum dosage = 60 mg/day) in 30 patients with obsessive-compulsive disorder (OCD). In the 8-week discontinuation phase, mirtazapine was significantly more effective than placebo in preventing symptom recurrence.

Mirtazapine augmentation of citalopram was assessed in 49 nondepressed OCD patients (Pallanti et al. 2004). Subjects were treated with citalopram plus placebo or citalopram plus mirtazapine under single-blind conditions. Mirtazapine appeared to speed the response to citalopram but not to improve overall response.

Sleep Disorders

Because of its sedating properties in depression, mirtazapine has recently been studied in patients with primary sleep disorders. In a double-blind crossover study in 7 patients with obstructive sleep apnea, mirtazapine dosages of 4.5 and 15 mg/day produced significantly greater reductions (on the order of 46%–52%) in apnea-hypopnea index (AHI) scores in comparison with placebo (Carley et al. 2007). However, the authors' concerns regarding weight gain and sedation led them to not recommend it at this time as a primary therapy.

Chronic or Recurrent Pain

A number of case reports indicate mirtazapine could be beneficial in chronic recurrent pain. A 56-year-old man with an 11-year history of treatment-refractory cluster headaches who was treated for 6 weeks with mirtazapine (30 mg/day) experienced rapid reduction in frequency and intensity of cluster attacks, with a concomitant decreased need for interventions, such as oxygen therapy and sumatriptan (Nutt 1999). A 47-year-old man with chronic pain symptoms resulting from a severe fall injury and major depression was treated unsuccessfully with amitriptyline, fluoxetine, and bupropion; however, the patient demonstrated significant improvement in symptoms of depression and pain, beginning 1 month after initiating mirtazapine (Brannon and Stone 1999). Another case report described a patient who was successfully treated with mirtazapine for major depression. The patient was also able to successfully abort migraine headaches with an extra dose of 7.5 mg of mirtazapine (Brannon et al. 2000). Finally, another report on four patients with phantom limb pain noted improvement in all cases (Kuiken et al. 2005).

A large series of 600 patients with comorbid pain and depression treated with mirtazapine has been reported in Germany (Freynhagen et al. 2006). The drug appeared to reduce pain effectively in this sample, with a relatively low-order risk of side effects (7%) at a mean dose of 35 mg/day.

The drug at 15–30 mg/day has also been reported to be effective in a double-blind crossover study in 24 nondepressed patients with chronic tension headaches (Bendtsen and Jensen 2004). Area under the curve (intensity times duration) for headache was significantly lower for drug than placebo.

Oncology

Theobold (2000) described a case of a 59-year-old patient with B-cell lymphoma recurrence treated with mirtazapine with a resolution of symptoms of depression, combined with a significant improvement in prior symptoms of anorexia and weight loss, by the end of 6 weeks of treatment.

A case series of 20 breast cancer and gynecological patients treated with mirtazapine demonstrated a significant reduction in symptoms of depression, anxiety, nausea, anorexia, and insomnia in 19 of the patients, as well as a lack of adverse drug interactions when combined with the usual treatment regimen, including chemotherapy (Thompson 2000).

A 7-week open-label, crossover trial of mirtazapine in 20 patients with cancer revealed significant improvements in mood, anxiety, insomnia, appetite, weight, and pain symptoms by the study endpoint (Theobold et al. 2002).

It has been suggested that mirtazapine could prove to be a safe and effective adjunct to cancer chemotherapy because of its ability to treat nausea via a 5-HT_3 receptor antagonism effect; insomnia, anorexia, and weight loss via H_1 receptor antagonism; symptoms of depression via enhanced 5-HT and noradrenergic transmission by way of α_2, 5-HT_2, and 5-HT_3 receptor blockade; and symptoms of

anxiety via 5-HT_2 and 5-HT_3 receptor antagonism (Kast 2001).

Obstetrics/Gynecology

A review of seven cases of pregnant patients with treatment-refractory hyperemesis gravidarum and symptoms of depression and anxiety revealed that treatment with mirtazapine resulted in resolution of symptoms without adverse impact on the newborns (Saks 2001).

Waldinger et al. (2000) described four cases in which women (ages between 39 and 60 years) experienced a near-complete resolution of symptoms of hot flushes and perspiration within the first week of treatment with mirtazapine.

An 8-week open-label trial of mirtazapine in 22 menopausal patients receiving estrogen replacement therapy who had major depression demonstrated an almost 90% remission rate among the study completers (Joffe et al. 2001).

Pediatric Depression and Anxiety

Mirtazapine has been assessed in several trials involving children or adolescents with major depression or anxiety disorders. In one trial of 24 adolescents with major depression, patients responded well to the drug, with no dropouts due to side effects (Haapasalo-Pesu et al. 2004). In another small open-label trial in 18 patients with social phobia, mirtazapine also demonstrated efficacy (Mrakotsky et al. 2008). Although there was a very high dropout rate, most of the discontinuations were not due to side effects.

Pervasive Developmental Disorders

In an open-label study on the use of mirtazapine in 26 patients with pervasive developmental disorders, 35% of subjects demonstrated significant improvement on CGI scores with respect to symptoms of aggression, self-injury, irritability, hyperactivity, anxiety, depression, and insomnia (Posey et al. 2001).

Depression in Alzheimer's Disease

Raji and Brady (2001) described three cases of patients with comorbid Alzheimer's dementia (Mini-Mental State Exam [MMSE] scores of 21/30, 11/30, and 18/30) and depressive symptomatology who were treated safely with mirtazapine. The patients demonstrated significant improvement in appetite, weight loss, sleep disturbances, anxiety, mood, anhedonia, and energy level.

Schizophrenia

The utility of mirtazapine in the treatment of the negative symptoms of schizophrenia has been examined. In a 6-week double-blind, randomized, placebo-controlled trial, addition of mirtazapine to haloperidol in the treatment of schizophrenia demonstrated a statistically significant reduction in Positive and Negative Syndrome Scale (PANSS) scores, as well as in CGI–Severity and CGI–Improvement scores (Berk et al. 2001). In addition, PANSS negative symptom scores in this study were found to be reduced by 42% in the group of patients who received adjunctive mirtazapine, compared with the group who received placebo (Berk et al. 2001). Furthermore, the latter finding was not correlated with Ham-D scores at study endpoint, which suggests that the effect of mirtazapine on diminution of negative symptoms in schizophrenia is not a result of improvement in mood symptoms (Berk et al. 2001).

Akathisia

Poyurovsky et al. (2003, 2006) conducted two double-blind, placebo-controlled studies of mirtazapine treatment of antipsychotic-induced akathisia in patients with schizophrenia. In the first study (Poyurovsky et al. 2003), mirtazapine 15 mg/day was compared with placebo in 26 patients. The drug

was significantly superior to placebo. In the second study (Poyurovsky et al. 2003), mirtazapine at the same dose was compared with propranolol 80 mg/day or placebo in 90 patients. Both drugs separated from placebo, but propranolol was associated with significantly greater bradycardia and hypotension.

SIDE EFFECTS AND TOXICOLOGY

In an open-label study of 103 outpatients with DSM-IV major depressive disorder, the most commonly reported side effects with mirtazapine were somnolence (49.5%), increased appetite (29.7%), and weight gain (22.8%) (Fava et al. 2001).

In a double-blind, placebo-controlled study of outpatients with depression, somnolence, increased appetite, and weight gain were the most commonly reported side effects associated with mirtazapine treatment (Claghorn and Lesem 1995).

In a review of data from the clinical development program for mirtazapine, the only adverse effects that occurred at a higher incidence with mirtazapine versus placebo were excessive sedation, increased appetite, weight gain, and dry mouth (Montgomery 1995). Also reported in this review was the observation that these side effects were typically mild and transient in nature and that they decreased with time and often diminished with increased dose (Montgomery 1995).

Side effects typical of SSRIs, such as nausea, diarrhea, and sexual dysfunction, appear to occur less frequently in patients treated with mirtazapine (Boyarsky et al. 1999; Farah 1998; Montgomery 1995; Stimmel et al. 1997).

Mirtazapine also appears to be well tolerated in elderly patients. The most common side effects reported, including somnolence, increased appetite, weight gain, and dry mouth, are of the same type as those reported in younger adults (Fawcett and Barkin 1998b; Halikas 1995).

Mirtazapine appears to have a very low incidence of causing clinically relevant laboratory abnormalities, such as transient rise in liver enzymes (2%) and severe neutropenia (0.1%) (Claghorn and Lesem 1995; Fawcett and Barkin 1998b; Kent 2000; Montgomery 1995).

Mirtazapine appears to have no clinically significant effects on seizure threshold or on the cardiovascular system (Claghorn and Lesem 1995; Fawcett and Barkin 1998b; Kent 2000; Montgomery 1995).

Of note, the noradrenergic effects of mirtazapine appear to be dose dependent and increase significantly at dosages >15 mg/day. As such, sedation associated with the affinity for H_1 receptors and typically experienced at dosages of ≤15 mg/day may be counteracted by an increasing noradrenergic neurotransmission at dosages ≥30 mg/day (Claghorn and Lesem 1995; Kent 2000). Likewise, it is also hypothesized that the risk of weight gain with mirtazapine is diminished at dosages ≥30 mg/day (Barkin et al. 2000; Fawcett and Barkin 1998b).

Use During Pregnancy and Lactation

A recent study conducted across six countries (Djulus et al. 2006) assessed the risk associated with exposure to mirtazapine during pregnancy. Birth outcomes were examined for three groups: pregnant women taking mirtazapine, disease-matched pregnant women taking other antidepressants, and pregnant women exposed to nonteratogens. There were approximately 100 patients per group. The rate of spontaneous abortions in the mirtazapine group (19%) was similar to that in the other antidepressant group (17%) and in the nonteratogen control group (11%). The rate of prematurity was significantly higher in the mirtazapine group (10%) versus the nonteratogen group (2%). The prematurity rate in the group taking other antidepressants was 7%. The rate of major malformations was not elevated in the mirtazapine group.

In a study of 8 women taking mirtazapine while breast feeding, concentrations of mirtazapine or desmethylmirtazapine were measured in milk and plasma (Kristensen 2007). Low infant doses were

observed, leading the authors to conclude that the drug is safe for lactating women who breast feed.

Overdose

Mirtazapine appears to be safe in overdose. In one report (Holzbach et al. 1998), the cases of two patients who had overdosed with 30–50 times the average daily dose of mirtazapine were presented. In each case, the patient recovered fully and without any complications. The first patient was a 44-year-old woman with a diagnosis of major depression who attempted suicide with 900 mg of mirtazapine, combined with an unknown quantity of amitriptyline and 0.5 L of wine. On admission to the hospital, the patient was somnolent and depressed but with normal vital signs, electrocardiogram, and neurological examination.

The second patient reported by Holzbach et al. (1998) was a 51-year-old woman with a diagnosis of major depression who attempted suicide with 1,500 mg of mirtazapine and 1 L of wine. Somnolence, minor sinus tachycardia, and mild leukocytosis were noted in this patient on admission to the hospital.

Overall, symptoms reported in cases of mirtazapine overdose include disorientation, drowsiness, impaired memory, and tachycardia (Fawcett and Barkin 1998b; Kent 2000; Montgomery 1995; Stimmel et al. 1997).

A review of 117 mirtazapine overdoses (average ingestion: 450 mg) in Scotland revealed the adverse consequences to be relatively mild (Waring et al. 2007). Decreased consciousness was seen in 27% of subjects; 30% demonstrated tachycardia.

DRUG–DRUG INTERACTIONS

In vitro data suggest that mirtazapine is unlikely to have clinically significant effects on the metabolism of drugs by cytochrome P450 enzymes (Barkin et al. 2000; Fawcett and Barkin 1998b; Kent 2000). Analysis of data from the clinical development program for mirtazapine and postmarketing surveillance reveal no clinically relevant drug–drug interactions occurring with the concomitant use of medications, such as opiates, anticonvulsants, analgesics, antihypertensives, diuretics, or nonsteroidal anti-inflammatory drugs (NSAIDs) (Barkin et al. 2000; Fawcett and Barkin 1998b). However, few formal drug interaction studies involving mirtazapine have been performed (Barkin et al. 2000; Fawcett and Barkin 1998b; Holm and Markham 1999). Of note, a recent study of elderly patients with depression allowed for patients to be on drugs that are CYP2D6 substrates (Schatzberg et al. 2002). In this latter study, no increase in side effects was observed in these patients, compared with patients who were not taking CYP2D6 substrate agents (Schatzberg et al. 2002).

CONCLUSION

In conclusion, mirtazapine is derived from the piperazinoazepine class of compounds and, as such, is structurally unrelated to any other psychotropic medication. Mirtazapine is also unique as an antidepressant because of its 5-HT_2, 5-HT_3, and α_2 receptor antagonist pharmacodynamic profile, which results in enhancement of noradrenergic and serotonergic transmission. It is an antidepressant that has been shown to be efficacious and well tolerated in the treatment of depression, and there are suggestions that it may be effective in a number of other medical and psychiatric conditions. Mirtazapine has also been suggested as a treatment intervention that may offer a more rapid amelioration of symptoms of depression and anxiety, compared with other antidepressants. The most common side effects reported with mirtazapine include somnolence, increased appetite, weight gain, and dry mouth. It otherwise appears to be a medication that is free of many of the adverse effects typical of the SSRIs, especially sexual dysfunction.

Furthermore, mirtazapine appears to be well tolerated and equally effective in the treatment of geriatric depression. In addition, mirtazapine appears to be safe in overdose, with case reports documenting complete and uncomplicated recovery following ingestion of up to 50 times the average

daily dose. Finally, mirtazapine appears devoid of clinically significant drug–drug interactions, although larger formal clinical trials are still needed to verify this.

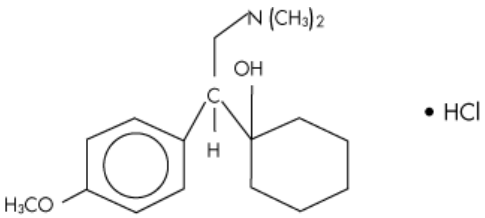
Chapter 22. Venlafaxine and Desvenlafaxine

HISTORY AND DISCOVERY



The drug known as venlafaxine was first synthesized in the early 1980s and was found to block the uptake of serotonin (5-HT) and, with lower potency, norepinephrine (NE), in rat brain synaptosomal preparations (Muth et al. 1986). Subsequently, it was shown to have in vivo activity in animal models of depression and to have little affinity for muscarinic or histaminergic postsynaptic receptors (Bolden-Watson and Richelson 1993; Muth et al. 1986). As such, venlafaxine was predicted to have a better tolerability profile than the tricyclic antidepressants (TCAs). Several early randomized, controlled trials (RCTs) confirmed that venlafaxine had antidepressant effects comparable to those of TCAs, with fewer side effects attributable to anticholinergic and antihistaminergic activity (see, for example, T. R. Einarson et al. 1999). The initial formulation of venlafaxine—now known as venlafaxine immediate-release (IR)—was approved by the U.S. Food and Drug Administration (FDA) for treatment of depression in 1994. An extended-release (XR) formulation was introduced a little more than 3 years later. Generic formulations of venlafaxine IR began to be introduced in 2007.

O-desmethylvenlafaxine (ODV), or simply desvenlafaxine, the primary active metabolite of venlafaxine, was introduced in 2008 as desvenlafaxine succinate, a sustained-release formulation for treatment of depression. Like venlafaxine, desvenlafaxine is classified as a serotonin–norepinephrine reuptake inhibitor (SNRI) and has minimal effects on other neurotransmitter receptors. Desvenlafaxine was developed in the hope of improving on the strengths of the parent drug. In vitro studies indicate that desvenlafaxine is somewhat more potent for blockade of norepinephrine transporters than the parent drug; the succinate salt was chosen to enhance bioavailability (Deecher et al. 2006). To date, desvenlafaxine's efficacy has been established in a series of placebo-controlled RCTs of major depressive disorder (MDD).

STRUCTURE–ACTIVITY RELATIONS

Venlafaxine and desvenlafaxine are bicyclic phenylethylamine compounds and are structurally and chemically unrelated to all other available antidepressants and anxiolytics, including other antidepressants classified as SNRIs (Figure 22–1).

PHARMACOLOGICAL PROFILE

As noted above, venlafaxine and desvenlafaxine inhibit the neuronal reuptake of 5-HT and NE in in vitro and ex vivo experimental paradigms (Bolden-Watson and Richelson 1993; Muth et al. 1986; Owens et al. 1997). Venlafaxine and desvenlafaxine do not inhibit the enzyme monoamine oxidase and have little or no in vitro affinity for muscarinic, cholinergic, histaminergic H_1, and α-adrenergic receptors (Bolden-Watson and Richelson 1993; Muth et al. 1986).

PHARMACOKINETICS AND DISPOSITION

After oral administration, venlafaxine and desvenlafaxine are well absorbed from the gastrointestinal tract and undergo extensive first-pass metabolism in the liver. Given that ODV is the only major metabolite of venlafaxine with relevant activity, desvenlafaxine has no active metabolites. Coadministration with food decreases the rate but not the extent of absorption (Troy et al. 1997b). Peak plasma concentrations are achieved within 2 hours for venlafaxine and within 3 hours for ODV following ingestion of the IR formulation (Troy et al. 1995b). Venlafaxine XR is absorbed more slowly than the IR formulation (peak plasma concentrations are achieved within 5.5 hours for venlafaxine and within 9 hours for ODV), resulting in lower peak and higher trough plasma concentrations. The extent of absorption and bioavailability of the two formulations of venlafaxine is comparable (Troy et al. 1997a). Steady-state plasma concentrations of both the parent drug and ODV are reached within 3–4 days of therapy.

Venlafaxine exhibits linear kinetics over a dosage range of 75–450 mg/day (Klamerus et al. 1992). The same is true for ODV across a range of 50–400 mg/day. Renal elimination is the primary route of excretion for both venlafaxine and ODV (S. R. Howell et al. 1993). Clearance of ODV (half-life = 10 hours) is slower than that of venlafaxine (half-life = 4 hours); therefore, most patients treated with venlafaxine have higher steady-state plasma concentrations of ODV than of the parent drug (Klamerus et al. 1992). Both venlafaxine and ODV are minimally bound to plasma albumin at therapeutic concentrations (27% and 30%, respectively).

The recommended starting dosage of venlafaxine is 75 mg/day (either divided into two or three doses of the IR or once-daily dosing of the XR formulation) for most therapeutic indications; a lower starting dosage may be used when treating the elderly or patients with a

history of tolerability problems. The IR formulation is available in 25-, 37.5-, 50-, 75-, 100-, and 150-mg tablets. The XR formulation is available in 37.5-, 75-, and 150-mg capsules; attempts to develop a larger dosage strength failed because some people found that the size of capsule was too large to easily swallow. Once-daily dosing with the XR formulation achieves bioavailability (i.e., >90%) nearly equivalent to that of twice-daily dosing with the IR formulation (Troy et al. 1997a). The XR formulation may be taken in either the morning or evening, and bioavailability is not affected by coadministration with food (Troy et al. 1997a).

The recommended starting dose of desvenlafaxine is 50 mg/day. A larger (100-mg) capsule is also available.

The results of fixed-dose studies of venlafaxine suggest dose-dependent efficacy in MDD (Kelsey 1996; Khan et al. 1998; Rudolph et al. 1998c; Thase et al. 2006b). Perhaps most importantly, a large amount of data from RCTs suggests that patients who do not respond to lower dosages often benefit from dosage increases (Costa e Silva 1998; Diaz-Martinez et al. 1998; Dierick et al. 1996; Mehtonen et al. 2000; Thase et al. 2006b). As reviewed elsewhere (Thase 2006), there is relatively little evidence of a dose–response relationship in treatment of anxiety disorders. Whereas the original form of venlafaxine was approved for treatment at doses of up to 375 mg/day (divided bid or tid), the manufacturer "capped" the recommended maximum daily dosage of XR at 225 mg because of a lack of data on the safety and tolerability of once-daily therapy at higher doses. Although some clinicians disregard this arbitrary restriction, it is true that the incidence of elevated blood pressure during venlafaxine therapy is heavily dose dependent (Thase 1998), and if only for this reason, vigilance is warranted when higher-dose therapy is indicated.

Less is known about the dose–response characteristics of desvenlafaxine. Early experiences with the compound in RCTs of MDD suggested that dosages above 200 mg/day may convey no additional efficacy and have a significantly higher incidence of side effects (DeMartinis et al. 2007; Septien-Velez et al. 2007). Although the full therapy development program has not yet been published, the minimum therapeutic dosage is 50 mg/day, and dosages above 100 mg/day are not recommended by the manufacturer. Whether patients who do not respond to 50 mg/day will benefit from upward titration to higher dosages has not yet been demonstrated.

Clearance of venlafaxine and desvenlafaxine is reduced among patients with cirrhosis or severe renal disease (Troy et al. 1994); therefore, dosing should be adjusted downward accordingly. In the absence of formal studies to inform such decisions, a 50% reduction in dosage and slower titration (i.e., at least 7–10 days between adjustments) of both the parent drug and desvenlafaxine are generally recommended. In otherwise healthy elders, adjustments in dosing of venlafaxine do not appear to be necessary (Klamerus et al. 1996). However, initiation of treatment with a lower starting dose, and slower subsequent titration, is a sensible approach when treating frail elders or medically complicated patients. Specific studies of desvenlafaxine in older, medically complex patients have not yet been undertaken.

MECHANISM OF ACTION

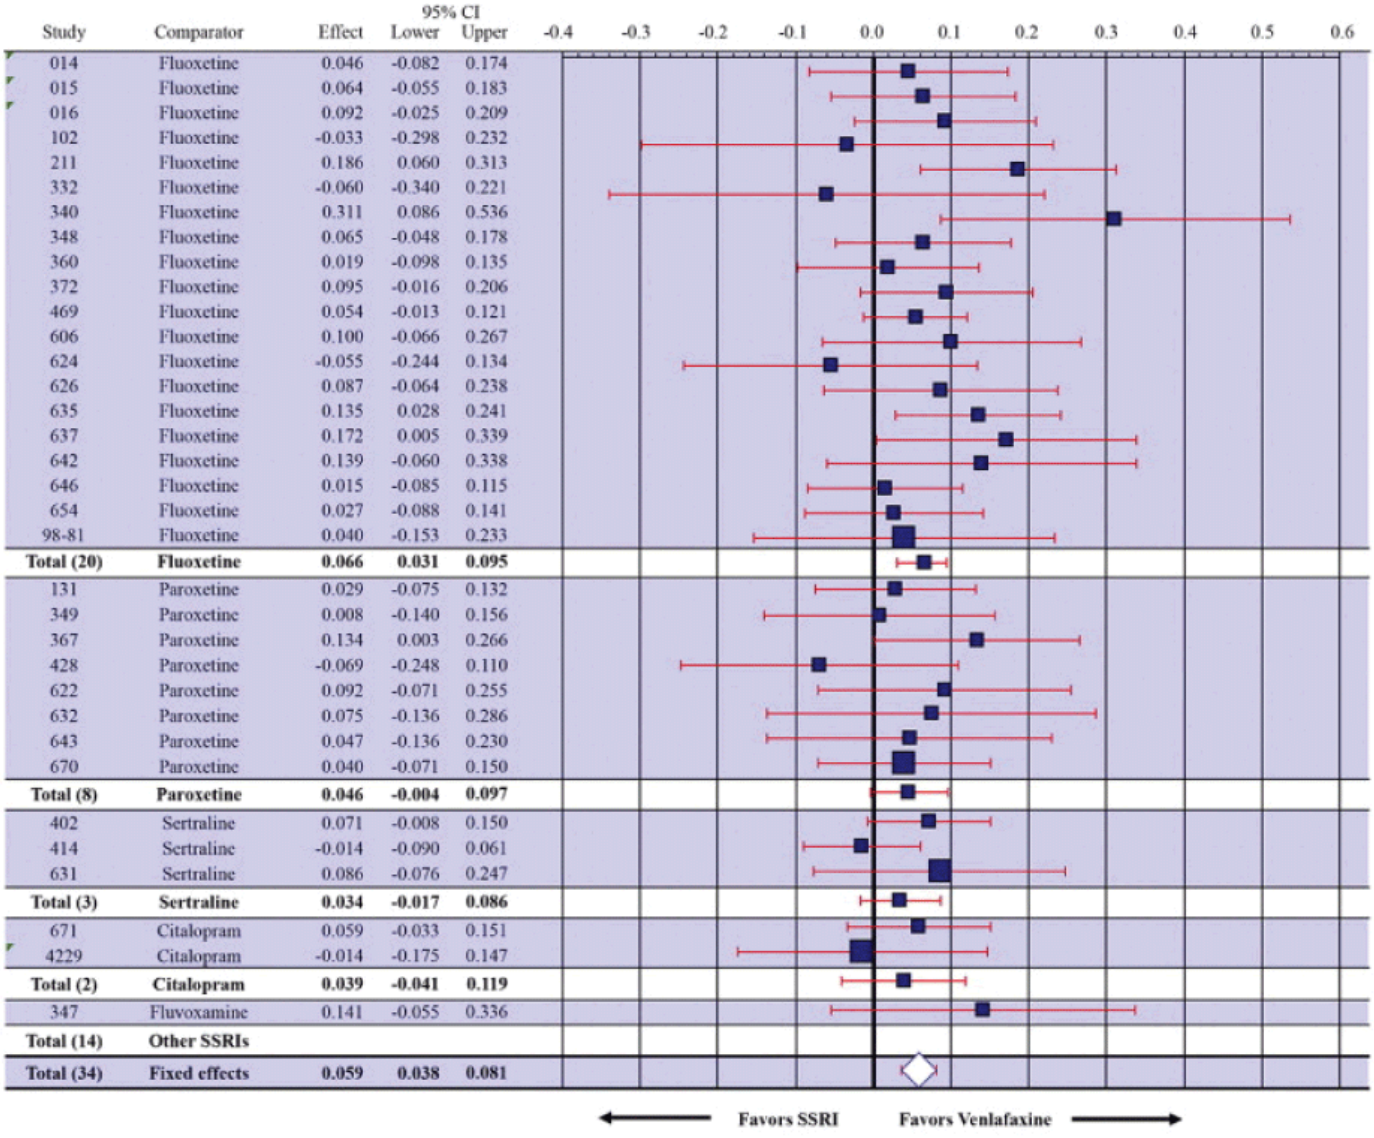
The mechanism of action of both venlafaxine and desvenlafaxine is believed to be inhibition of 5-HT and NE reuptake. From the beginning, comparisons with the first medication to be considered a "dual reuptake inhibitor," the TCA clomipramine, have been inevitable. Venlafaxine is also a weak inhibitor of dopamine reuptake in vitro (Muth et al. 1986), although this effect probably is not clinically significant at routine therapeutic doses. Consistent with this view are the results of one recent in vivo study of healthy volunteers, which found essentially no blockade of the dopamine transporter with venlafaxine dosages of 75 and 150 mg/day (Shang et al. 2007).

There is good evidence that venlafaxine and desvenlafaxine are more potent inhibitors of 5-HT reuptake than of NE reuptake (Bolden-Watson and Richelson 1993; Deecher et al. 2006; Vaishnavi et al. 2004). It has long been suggested that this relationship underpins the ascending dose–response relationship of venlafaxine (Kelsey 1996; Thase 1996). Moreover, some argue that venlafaxine is essentially an SSRI at the lowest therapeutic dosage (i.e., 75 mg/day) and that the noradrenergic effect is progressively recruited as the dose is increased (Kelsey 1996). There are both experimental (Harvey et al. 2000) and clinical (Davidson et al. 2005; R. Entsuah and Gao 2002; Rudolph et al. 1998a; Thase 1998; Thase et al. 2006b) data that are consistent with such a relationship. Nevertheless, significant effects on autonomic measures of noradrenergic function are evident at 37.5- and 75-mg/day dosages (Bitsios et al. 1999; Siepmann et al. 2007). Until it is possible to directly image NE transporter occupancy in vivo, this question cannot be definitively answered.

INDICATIONS AND EFFICACY

Venlafaxine XR is approved by the FDA for the treatment of MDD, generalized anxiety disorder (GAD), social anxiety disorder, and panic disorder. Venlafaxine IR and desvenlafaxine are approved only for the treatment of MDD.

Although venlafaxine has not been formally approved for treatment of other psychiatric disorders, there is evidence that it also has efficacy in other disorders that are responsive to SSRIs, including obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), and premenstrual dysphoric disorder (PMDD). Given that desvenlafaxine is the active metabolite of venlafaxine, it is likely to be effective in every disorder that is responsive to the parent drug.



Major Depressive Disorder

The antidepressant efficacy of venlafaxine has been established in a large number of placebo-controlled, randomized trials (Cunningham 1997; Guelfi et al. 1995; Khan et al. 1991; Mendels et al. 1993; Rudolph et al. 1998c; Schweizer et al. 1991; Shrivastava et al. 1994; Thase 1997), including studies focusing on depressed patients with associated symptoms of anxiety (Feighner et al. 1998; Khan et al. 1998; Rudolph et al. 1998b). In published studies employing SSRIs as active comparators, venlafaxine therapy has been found to be comparable or superior to therapy with fluoxetine (Alves et al. 1999; Clerc et al. 1994; Costa e Silva 1998; De Nayer et al. 2002; Dierick et al. 1996; Keller et al. 2007a; Nemeroff and Thase 2007; Rudolph and Feiger 1999; Rudolph et al. 1998a; Schatzberg and Roose 2006; Silverstone and Ravindran 1999; Tylee et al. 1997; Tzanakaki et al. 2000), sertraline (Mehtonen et al. 2000; Rush et al. 2006; Shelton et al. 2006; Sir et al. 2005), paroxetine (Ballus et al. 2000; McPartlin et al. 1998; Poirier and Boyer 1999), and citalopram (Allard et al. 2004). Results of two studies comparing venlafaxine and escitalopram have yielded somewhat conflicting results (Bielski et al. 2004; Montgomery et al. 2004b), with comparability in the latter study and trends favoring the SSRI in the former study, which employed rapid titration to maximum FDA-approved doses (Bielski et al. 2004). A pooled analysis of these two trials also found a significant advantage for escitalopram among the subset of patients with higher pretreatment depression severity (Montgomery and Andersen 2006). Comparative studies of desvenlafaxine and SSRIs are under way, but results are not yet available.

Results from meta-analyses of early published and unpublished studies comparing venlafaxine and SSRIs provided some evidence that venlafaxine may produce a significantly greater antidepressant response than fluoxetine and perhaps than SSRIs as a class (T. R. Einarson et al. 1999; Smith et al. 2002; Stahl et al. 2002; Thase et al. 2001). In the meta-analysis by Thase et al. (2001), for example, the magnitude of this effect was a 10% higher rate of remission (as defined by a total score of 7 or less on the 17-item Hamilton Rating Scale for Depression), which was comparable to the magnitude of the effect favoring the SSRIs over placebo. The advantage versus fluoxetine was subsequently confirmed by an independent meta-analysis conducted by the Cochrane group (Cipriani et al. 2006), although this was not observed in the largest prospective head-to-head RCT (Keller et al. 2007a), which examined the outcomes of 1,096 patients with recurrent MDD across 10 weeks of double-blind therapy.

Results of the most comprehensive meta-analysis of RCTs comparing venlafaxine and SSRIs undertaken to date are consistent with the hypothesis that venlafaxine therapy has significantly greater efficacy than fluoxetine alone and than the SSRIs as a class (Nemeroff et al. 2008). Working with individual patient data from all of the manufacturer-sponsored double-blind RCTs conducted worldwide (*N* = 34 studies), the antidepressant efficacy of venlafaxine, various SSRIs (fluoxetine, paroxetine, sertraline, citalopram, or fluvoxamine), and placebo (9 studies) across up to 8 weeks of therapy were compared in more than 8,500 adults with MDD. The absolute difference in remission rates was found to be 6%, favoring the SNRI (95% confidence interval = 3.8%–8.1%) (Figure 22–2). The difference was again statistically significant for the more numerous studies using fluoxetine as a comparator but not for the comparisons of the other SSRIs individually. A secondary analysis utilizing the funnel plot method, which also included results of all other known comparative studies of venlafaxine and SSRIs, yielded confirmatory results (Nemeroff et al. 2008). Although statistical significance was observed, the modest magnitude of the difference across studies falls below the standard for clinical significance suggested by the Cochrane group (e.g., Cipriani et al. 2006).

Remission is defined as a 17-item Hamilton Rating Scale for Depression (Ham-D-17) score of 7 or less for 33 of the 34 studies. One study (4229; Allard et al. 2004) did not use the Ham-D, and remission was defined as a Montgomery-Åsberg Depression Rating Scale score of 10 or less. Remission rate differences for the individual studies ranged from –7% to 31%; differences numerically favored venlafaxine in 28 studies (although only 5 reached statistical significance), with 6 studies numerically favoring the SSRIs.

With respect to other newer antidepressants, two studies comparing venlafaxine and mirtazapine therapies (Benkert et al. 2006; Guelfi et al. 2001) found trends favoring the latter compound early in the course of treatment but comparable efficacy at study endpoint. Mirtazapine, which is a potent blocker of histamine and 5-HT_2 receptors, also had a significant advantage in relief of insomnia in both of these studies. One relatively large outpatient study contrasting bupropion, a norepinephrine–dopamine reuptake inhibitor (NDRI), and venlafaxine XR found a comparable overall pattern of efficacy, with the NDRI having a significant advantage in terms of a lower incidence of sexual side effects and a higher proportion of patients achieving remission at study endpoint (Thase et al. 2006a). The latter finding, which was discrepant from levels of symptom reduction and response rates, may be attributable to the special nature of the study population (i.e., relatively younger, sexually active patients). A pair of studies contrasting venlafaxine and the other widely available SNRI, duloxetine, found no differences in efficacy at either the primary or secondary study endpoints (Perahia et al. 2008). In the pooled data set of those two studies, several tolerability indices favored venlafaxine early in the course of therapy, whereas there were fewer discontinuation symptoms in the duloxetine group following cessation of study therapy.

Several studies have evaluated the utility of venlafaxine therapy in bipolar depression. In the first, a double-blind, placebo-controlled study, the efficacy and safety of venlafaxine treatment were compared in 17 patients with bipolar II disorder and 31 patients with unipolar depression (Amsterdam 1998). Patients were randomly assigned to 6 weeks of double-blind treatment with once- versus twice-daily venlafaxine IR (up to 225 mg/day). Overall, similar efficacy was observed in unipolar and bipolar patients, although a more rapid reduction of symptoms was observed by week 2 of treatment among bipolar patients who completed the entire trial. No episodes of drug-induced hypomania or rapid cycling were observed.

Vieta et al. (2002) compared therapy with venlafaxine or paroxetine in a double-blind study of 60 bipolar I patients taking concomitant mood stabilizers. Results suggested comparable efficacy and tolerability, although the patients treated with venlafaxine had a higher rate of treatment-induced mania (13%) than the group treated with paroxetine (3%).

Venlafaxine was contrasted with bupropion and sertraline in 174 bipolar I and II patients taking concomitant mood stabilizers (Post et al. 2006). Again, there was no difference in efficacy, but the rate of treatment-emergent affective switches was significantly higher for the patients randomly assigned to the SNRI compared with those assigned to the other two antidepressants.

Venlafaxine is one of the preferred choices for patients who have not responded to other first-line antidepressants (Thase et al. 2000). Two recent RCTs compared venlafaxine with other treatment options after nonresponse to an initial course of SSRI therapy (Baldomero et al. 2005; Rush et al. 2006). Despite a number of differences in design, these studies yielded almost identical results, with a modest numeric advantage in remission rates for the SNRI versus a second trial within the SSRI class. Results were statistically significant in a larger study (Baldomero et al. 2005), which was conducted in Spain, but did not reach significance in the smaller study, which was conducted in the United States as part of the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) project (Rush et al. 2006). Another study within the STAR*D program contrasted the combination of venlafaxine and mirtazapine (*n* = 51) versus the monoamine oxidase inhibitor (MAOI) tranylcypromine (*n* = 58) among MDD patients who had not responded to three consecutive prospective medication trials (McGrath et al. 2006). Although the two strategies did not differ with respect to the primary outcome variable (remission rates were only 14% and 7% for the combination and MAOI strategies, respectively), patients treated with the combination strategy had significantly greater symptom reduction and a higher study completion rate than patients treated with the MAOI.

Venlafaxine has not been studied in combination with antipsychotic medication for patients with psychotic depression. One study did, however, compare double-blind therapy with either venlafaxine IR (300 mg/day) or fluvoxamine (300 mg/day) as monotherapies in 28 psychotically depressed patients (Zanardi et al. 2000). Findings strongly favored the group receiving fluvoxamine (response rates: 79% vs. 50%), although such an apparently large difference was not statistically significant in this small study. Regardless, venlafaxine should not be thought of as a stand-alone therapy for patients with psychotic depression.

Earlier longer-term open-label trials suggested that venlafaxine had sustained efficacy across 12 months of continued therapy (Magni and Hackett 1992; Tiller et al. 1992). Results of a pooled analysis of the extension phases of four randomized, double-blind, controlled studies in outpatients with major depression demonstrated that the rate of relapse at 6 months and 1 year was significantly lower in the venlafaxine-treated group than in the placebo-treated group (A. R. Entsuah et al. 1996). Double-blind, placebo-controlled studies subsequently confirmed the efficacy of venlafaxine treatment for prevention of relapse during 6 months of continuation treatment (Simon et al. 2004) and for prevention of recurrence during 12 months (Kocsis et al. 2007; Montgomery et al. 2004a) and 24 months (Keller et al. 2007b) of maintenance-phase therapy.

Generalized Anxiety Disorder

Venlafaxine XR was approved by the FDA for treatment of GAD on the basis of a series of placebo-controlled RCTs (Allgulander et al. 2001; Davidson et al. 1999; Gelenberg et al. 2000; Nimatoudis et al. 2004; Rickels et al. 2000), including two trials that evaluated efficacy across 6 months of therapy (Allgulander et al. 2001; Gelenberg et al. 2000). Across studies, the efficacy of doses ranging from 75 mg/day to 225 mg/day was established versus placebo, with little evidence of dose–response relationships for both efficacy and tolerability.

To date, there have been no studies of higher-dose venlafaxine therapy for GAD. Only a handful of studies have been completed comparing venlafaxine XR with other medications with established efficacy in GAD. Superiority to buspirone was found on some (but not all) measures in the one study that was undertaken (Davidson et al. 1999). In the single study that compared venlafaxine XR with the

benzodiazepine diazepam (Hackett et al. 2003), the two treatments were comparably effective, although neither active therapy was statistically more effective than placebo.

Two comparative studies have contrasted venlafaxine XR with SSRIs in GAD. In the first, a randomized but open-label trial comparing venlafaxine XR and paroxetine in 60 outpatients, Kim et al. (2006) reported comparable efficacy and tolerability. In the second study (Bose et al. 2008), a relatively large (*N* = 392) RCT, venlafaxine XR and escitalopram were contrasted. Overall, there were no significant differences between the two therapies. However, venlafaxine XR was statistically significantly more effective than placebo on the primary outcome measure (whereas escitalopram was not), and attrition due to side effects was significantly greater in the venlafaxine arm than in the placebo arm (whereas the difference in attrition between the escitalopram and placebo arms was not statistically significant).

Social Anxiety Disorder

Venlafaxine XR was approved for treatment of social anxiety disorder on the basis of a series of RCTs that confirmed its efficacy and safety relative to placebo across up to 6 months of double-blind therapy (Allgulander et al. 2004; Liebowitz et al. 2005a, 2005b; Rickels et al. 2004; Stein et al. 2005). As was the case in GAD, effective doses ranged from 75 mg/day to 225 mg/day, with little evidence of an ascending dose–response relationship. In the two studies that included paroxetine as an active comparator, venlafaxine therapy was at least as effective and as well tolerated as the SSRI (Allgulander et al. 2004; Liebowitz et al. 2005a).

Panic Disorder

Although promising results in panic disorder were apparent in an early placebo-controlled study utilizing the IR formulation (Pollack et al. 1996), the research that ultimately led to a formal FDA indication was largely delayed until after studies of the XR formulation were completed in MDD, GAD, and social anxiety disorder. Antipanic efficacy was demonstrated in three placebo-controlled studies of acute-phase therapy, including one 10-week flexible-dose study (Bradwejn et al. 2005) and two 12-week fixed-dose studies investigating 75 mg/day and 150 mg/day (Pollack et al. 2007a) or 75 mg/day and 225 mg/day (Pollack et al. 2007b). These studies, which incorporated a 37.5-mg starting dose to minimize early side effects, established an effective dosage range of 75–225 mg/day. Two of the placebo-controlled studies also included paroxetine (40 mg/day) as an active comparator (Pollack et al. 2007a, 2007b). Overall, two fixed doses of venlafaxine XR (75 mg/day and 150 mg/day) were comparable to paroxetine in both efficacy and tolerability. In the single RCT that included a fixed-dose 225-mg/day arm, the higher dose of venlafaxine therapy was significantly more effective than paroxetine on several secondary outcome measures, including the proportion of patients who experienced complete relief from full symptom panic attacks (70% vs. 58%) (Pollack et al. 2007b). Sustained efficacy was demonstrated in one longer-term study using a classic relapse prevention design, in which patients who responded to 12 weeks of open-label therapy with venlafaxine XR (75–225 mg/day) were randomly allocated to 6 additional months of double-blind therapy with either the active drug or placebo (Ferguson et al. 2007).

Other Anxiety Disorders

Early studies of venlafaxine therapy of PTSD have been reviewed by Pae et al. (2007). Results of two large RCTs demonstrated the efficacy of venlafaxine XR versus placebo (Davidson et al. 2006a, 2006b). The first trial, which enrolled 573 adults scoring at least 60 on the Clinician-Administered PTSD Scale (CAPS-SX17), compared venlafaxine XR (range = 37.5–300 mg/day; mean dosage = 225 mg/day), sertraline (range = 25–200 mg/day; mean dosage = 151 mg/day), and matching placebo across 12 weeks of double-blind treatment. Venlafaxine XR therapy was significantly more effective than placebo, as measured by change in CAPS-SX17 scores and remission rates at study endpoint, whereas sertraline was not. There were, however, no significant differences in efficacy between the two active therapies. Final remission rates were 30%, 24%, and 20% for the SNRI, SSRI, and placebo groups, respectively. In the second study, which enrolled 329 adults meeting the same entry criteria, venlafaxine XR (mean dosage = 222 mg/day) was compared with placebo across up to 6 months of double-blind therapy. The efficacy of the SNRI was documented by significant effects on all primary and secondary outcome measures, with final remission rates of 51% and 38% for the venlafaxine XR and placebo groups, respectively.

The results of an initial open-label case series (Rauch et al. 1996) suggested that venlafaxine would also be a useful treatment of OCD. Indeed, results of a 12-week single-blind study indicated that venlafaxine might be at least as effective as clomipramine and significantly better tolerated (Albert et al. 2002). However, the manufacturer did not pursue a large-scale registration program for this indication, and the smaller-scale studies that have been performed do not reveal particular advantages as compared to approved SSRIs such as paroxetine (see the review by Thase 2006).

Premenstrual Dysphoric Disorder

A randomized, double-blind, placebo-controlled study evaluated the efficacy of venlafaxine IR for the treatment of PMDD in 157 women treated across four menstrual cycles (Freeman et al. 2001). Dosages ranged from 50 mg/day to 200 mg/day, with adjustments for adverse events or lack of efficacy early in each cycle. Analysis of daily symptom rating scores revealed significantly greater improvement in the venlafaxine group compared with the placebo group at endpoint in the primary factors of emotion, function, physical symptoms, and pain. In a second small pilot study of intermittent (premenstrual) dosing, Cohen et al. (2004) treated 11 women with PMDD who had not responded to a single-blind placebo lead-in. Nine of the 11 responded to the two 14-day courses of venlafaxine XR 75–112.5 mg/day. The medication was well tolerated, and intermittent dosing was not associated with significant discontinuation symptoms. Further studies are needed to ascertain the longer-term efficacy of venlafaxine treatment for PMDD.

Treatment of Children and Adolescents

Venlafaxine XR was being evaluated for treatment of MDD, GAD, and social anxiety disorder in pediatric populations at the time that concerns about the potential for antidepressants to induce suicidal ideation and behaviors in children began to surface in 2003–2004. Although the manufacturer chose not to pursue further formal indications in any pediatric disorder, results of the five completed studies have been published and include a pair of studies in MDD (Emslie et al. 2007), two RCTs in GAD (Rynn et al. 2007), and one study in social anxiety disorder (March et al. 2007). Results in the depression studies (pooled *N* = 334) were mixed: venlafaxine XR was significantly more effective than placebo among participants ages 12–17 years but not among children ages 7–11 years. In the pooled data set, venlafaxine XR therapy was associated with an increased risk of treatment-emergent suicidal and aggressive behaviors compared with

placebo (Emslie et al. 2007). In the pair of GAD studies (pooled *N* = 330), venlafaxine XR was significantly more effective than placebo in the pooled data set; one study was unequivocally positive, but the second study failed to separate between drug and placebo on the primary dependent measure (Rynn et al. 2007). In the social anxiety disorder study (*N* = 293), venlafaxine XR also was significantly more effective than placebo on both primary and secondary outcome measures (March et al. 2007).

SIDE EFFECTS AND TOXICOLOGY

The side-effect profile of the IR formulation of venlafaxine was superior to the TCAs, although not quite as favorable as the SSRIs (Preskorn 1995). In the meta-analysis of Nemeroff et al. (2008), for example, 11% of the venlafaxine-treated patients withdrew from therapy because of adverse events, compared with 9% of patients treated with SSRIs. As an SNRI, the tolerability profile of venlafaxine includes all of the characteristic side effects associated with 5-HT uptake inhibition (i.e., nausea, insomnia, tremor, and sexual dysfunction) as well as side effects attributable to NE reuptake inhibition (i.e., sweating and dry mouth). The major advantage of the XR formulation, aside from permitting once-daily dosing, is a somewhat lower incidence of nausea during the first weeks of therapy (Cunningham 1997). To date, no comparative study of venlafaxine and an SSRI has included a detailed assessment of sexual dysfunction. The results of studies focused on detection of sexual dysfunction during antidepressant treatment suggest that venlafaxine and the SSRI are associated with similar risks (Clayton et al. 2002; Kennedy et al. 2000; Montejo et al. 2001).

Like the SSRIs, venlafaxine does not affect cardiac conduction and does not lower the seizure threshold (at least at therapeutic doses). Unlike the SSRIs, however, venlafaxine is associated with a small increase in pulse rate and a dose-dependent increased risk of elevated blood pressure (Thase 1998). Experience with the IR formulation in studies of MDD indicated that the risk of sustained high blood pressure increased from 3% to 7% at dosages of 100–225 mg/day and to 13% at dosages above 300 mg/day (Thase 1998). In the studies of the XR formulation, which limited the maximum dosage to 225 mg/day, the increased risk was only 3% in patients with MDD and 0.5% in patients with GAD. Nevertheless, the manufacturer continues to recommend that all patients receiving venlafaxine have regular monitoring of blood pressure. In practice, it is prudent to record blood pressure prior to initiating venlafaxine therapy and to monitor serially if dosages above 225 mg/day are prescribed. More careful monitoring is warranted for patients with preexisting high blood pressure and for the elderly.

Similar to most other antidepressants, venlafaxine is classified as pregnancy Category C, indicating that there are no adequate and well-controlled studies in pregnant women and that the drug should be used during pregnancy only if it is clearly needed. Results of a multicenter case–control study evaluating pregnancy outcome following gestational exposure to venlafaxine (*n* = 150), SSRIs (*n* = 150), or other drugs (*n* = 150) revealed no evidence that venlafaxine therapy increases the risk of major fetal malformations (A. Einarson et al. 2001).

As with other psychotropic medications, venlafaxine and its metabolites are excreted in human breast milk. Reports by Ilett et al. (1998, 2002) of the distribution of venlafaxine in human milk and its effects in breast-fed infants demonstrated that the mean infant dose exposure was approximately 6%–7% of the maternal dose, which is below the 10% notional level of concern. No adverse effects were noted in any of the infants (Ilett et al. 2002). Although these data support the use of venlafaxine in pregnant or breast-feeding women, the findings are preliminary, and the available safety data remain limited. The decision to use venlafaxine in pregnancy or lactation should be made on the basis of an individual risk–benefit assessment.

Precipitous withdrawal of venlafaxine can result in a characteristic "discontinuation" profile, including dizziness, dry mouth, insomnia, nausea, nervousness, sweating, anorexia, diarrhea, somnolence, and sensory disturbances (Haddad 2001). Venlafaxine therapy therefore should not be discontinued abruptly, and whenever possible, a taper schedule of no more than 75 mg/day/week is strongly recommended. It is important to note that the discontinuation schedule used in clinical trials was based on only 6- to 12-week durations of treatment. In practice, longer tapering schedules may be required, depending on the dose, the duration of therapy, and the individual patient. Clinicians should counsel patients about the possibility of adverse effects following abrupt discontinuation of treatment.

In the 13-plus years since its initial introduction, there has been extensive experience with venlafaxine overdose. A number of fatal overdoses have been reported, primarily involving combinations of venlafaxine and other drugs and/or alcohol (Banham 1998; Kunsman et al. 2000; Long et al. 1997; Parsons et al. 1996). In nonfatal overdoses, electrocardiogram changes (e.g., prolongation of QT interval, bundle branch block, QRS prolongation), sinus and ventricular tachycardia, bradycardia, hypotension, altered level of consciousness (ranging from somnolence to coma), serotonin syndrome, and seizures have been reported (C. Howell et al. 2007; Whyte et al. 2003). In an analysis of fatal poisoning with antidepressants in the United Kingdom, Buckley and McManus (2002) used a statistic known as the fatal toxicity index (FTI), which was defined by the number of overdose deaths per million prescriptions, to compare the relative risks of different antidepressants. They found that venlafaxine had a significantly higher FTI than the SSRIs (13.2 vs. 0.7–3.0). The authors suggested that these data could mean that venlafaxine should not be used as a first-line treatment for patients with suicidal ideation. However, many nonpharmacological factors can contribute to the likelihood of a fatal overdose, particularly patient risk factors. In this regard, two studies have documented that the patients who are selected for treatment with venlafaxine are at greater inherent suicide risk than are patients selected for treatment with SSRIs (Mines et al. 2005; Rubino et al. 2007). Adjustment for these risk factors greatly reduced the difference in FTI between venlafaxine and the SSRIs (Rubino et al. 2007). Although the potential for lethality in overdose certainly warrants ongoing study, the current state of the evidence does not indicate that venlafaxine therapy should be avoided in patients at risk for suicidal behavior.

DRUG–DRUG INTERACTIONS

Venlafaxine undergoes extensive metabolism in the liver by the cytochrome P450 (CYP) enzyme system, particularly by the CYP2D6 isoenzyme. Patients who are "poor CYP2D6 metabolizers," whether genetically or by taking drugs that inhibit this enzyme, thus have increased concentrations of the parent drug relative to ODV. Although it could be argued that this should not affect response, given that the parent drug and ODV are nearly pharmacologically equipotent, poor metabolizers of CYP2D6 may be at greater risk for side effects (McAlpine et al. 2007; Shams et al. 2006). Such patients thus could potentially be better candidates for therapy with desvenlafaxine than the parent drug.

Despite being a substrate for CYP2D6, venlafaxine and ODV are among the weakest of inhibitors of this isoenzyme (Alfaro et al. 2000;

Amchin et al. 2001; Ball et al. 1997). In vitro and in vivo studies have shown that venlafaxine and ODV cause little or no inhibition of other CYP isoenzymes, including 1A2, 2C9, 2C19, and 3A4 (Ball et al. 1997; Owen and Nemeroff 1998). Although it does not appear to have significant affinity for CYP3A4, venlafaxine has been shown to decrease blood levels of the protease inhibitor indinavir, a substrate of CYP3A4 (Levin et al. 2001). Neither the mechanism nor the clinical significance of this interaction is known, but it is of concern given the critical nature of treatment with protease inhibitors.

As SNRIs, both venlafaxine and desvenlafaxine are contraindicated in patients taking MAOIs, because of the risk of serotonin syndrome. This is as true for the newer transdermally delivered formulation of selegiline as it is with the older agents. As with cyclic antidepressants and SSRIs, venlafaxine or desvenlafaxine treatment should not be initiated until 2 weeks after discontinuation of an MAOI, and MAOI therapy should not be initiated until at least 7 days after discontinuation of venlafaxine or desvenlafaxine.

Venlafaxine and desvenlafaxine appear to have no clinically significant interactions with lithium (Troy et al. 1996), diazepam (Troy et al. 1995a), or alcohol (Troy et al. 1997c).

CONCLUSION

Venlafaxine, the first widely used member of the SNRI class, appears to be at least as effective as other first-line antidepressants and has an overall safety profile that is closer to the SSRIs than the TCA. There is evidence of a modest efficacy advantage compared with fluoxetine and perhaps to the SSRIs as a class, although to date a significant efficacy advantage has not been demonstrated against other specific members of the class, most particularly escitalopram. Venlafaxine also has established efficacy for treatment of GAD, social anxiety disorder, and panic disorder. Generic formulations of venlafaxine IR are now available, although the more heavily prescribed XR formulation, which is patent-protected for several more years, offers the advantages of once-daily dosing and a lower incidence of nausea during the first few weeks of therapy. ODV, the primary active metabolite of venlafaxine, was introduced as antidepressant (desvenlafaxine succinate) in 2008. Desvenlafaxine offers several advantages over venlafaxine XR in terms of simpler dosing (e.g., lower starting dose, lower minimum therapeutic dose, no active metabolite, and possibly less need for upward dosage titration); beyond this, however, the relative merits of the two drugs have not yet been assessed. Both drugs have a low potential for cytochrome P450–mediated drug–drug interactions and are associated with dose-dependent increases in blood pressure.

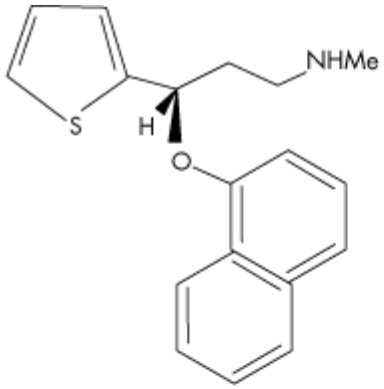
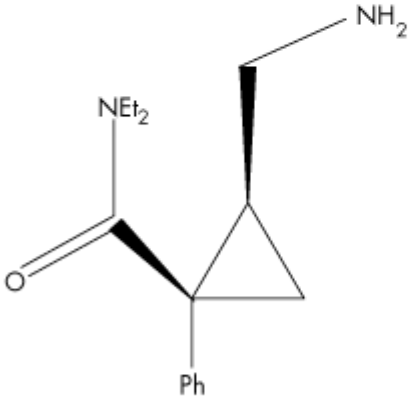
Chapter 23. Duloxetine and Milnacipran



DULOXETINE AND MILNACIPRAN: INTRODUCTION

Duloxetine was first synthesized in the 1980s and subsequently patented in 1991. The U.S. Food and Drug Administration (FDA) did not approve this drug for the treatment of major depressive disorder and diabetic neuropathy, however, until the third quarter of 2004. This long delay occurred because the drug was initially tested in depressed patients at low dosages of 5–20 mg/day, which were not efficacious. Duloxetine has received approval in most countries worldwide since then but became available in Canada only in 2008. It is also approved in the United States for generalized anxiety disorder and fibromyalgia. Milnacipran was approved in France for the treatment of depression in 1996 but only recently was approved for use in North America for patients with fibromyalgia.



STRUCTURE–ACTIVITY RELATIONS

Duloxetine and milnacipran (Figure 23–1), along with venlafaxine, are antidepressant medications that can act as serotonin (5-hydroxytryptamine; 5-HT) and norepinephrine reuptake inhibitors. Whereas selective serotonin reuptake inhibitors (SSRIs) target only the 5-HT transporter (5-HTT), the dual-acting medications have the potential to inhibit both the 5-HTT and the norepinephrine transporter (NET). Collectively, these three medications are referred to as serotonin–norepinephrine reuptake inhibitors (SNRIs). Several lines of evidence have to be considered, however, to determine at which concentrations SNRIs are indeed effective dual reuptake inhibitors. This is of crucial importance in estimating their potency in clinical settings.

PHARMACOLOGICAL PROFILES

In Vitro Assessments

The first data to consider in determining the biochemical profile of reuptake inhibitors are their affinity values for membranal carriers. These values can be calculated by determining the concentration of a medication necessary to displace 50% of the specific binding of a standard ligand for a given transporter subtype in a lyzed cell preparation (K_i). This technique generally provides rough estimates of the potential for drugs to inhibit reuptake. A somewhat more indicative approach consists of determining the concentrations of drugs necessary to inhibit the uptake of transmitters in intact cells from either animal brains or human cell lines. These physiological results are more reliable than mere binding data because of the integrity of the tissue. Indeed, recent data indicate that the binding of some norepinephrine reuptake blockers varies markedly when they are tested in membrane preparations versus intact cells, whereas with other agents, such as the tricyclic antidepressants (TCAs), it does not (Mason et al. 2007). As can be seen in Table 23–1, not only do the absolute potencies vary between the two preparations, their ratios vary as well.

In Vivo Assessments

Ideally, the potency of reuptake inhibitors in animal experiments should be assessed in vivo with the medications administered systemically. One common technique is to conduct microdialysis studies whereby extracellular levels of neurotransmitters are estimated from the perfusion of an artificial cerebrospinal fluid. Data generated with duloxetine in rats indicate that it first enhances brain levels of 5-HT, and that with increasing doses it increases norepinephrine levels (Koch et al. 2003). In the case of milnacipran, the levels of 5-HT and norepinephrine are generally enhanced to the same extent (in guinea pigs; Moret and Briley 1997), although pronounced regional differences have been observed. For instance, milnacipran is six times more potent in the rat hypothalamus than in the midbrain raphe nuclei and the frontal cortex (Bel and Artigas 1999). These results suggest that milnacipran may not readily penetrate the blood–brain barrier.

Potency can also be assessed in vivo using electrophysiological approaches. For instance, by determining the capacity of reuptake inhibitors to suppress the firing of 5-HT and norepinephrine neurons, reliable potency estimates can be obtained. As reuptake transporters are dose-dependently inhibited from their systemic injection, 5-HT and norepinephrine accumulate at the cell body level of such neurons that will activate their respective autoreceptors, thereby decreasing firing activity. Using this approach, duloxetine suppresses the firing rate of 5-HT neurons by 50% with an intravenous dose of 0.1 mg/kg and suppresses the firing rate of norepinephrine neurons to the same level with a dose of 0.5 mg/kg (Kasamo et al. 1996). This in vivo ratio of 1:5 is quite different from the in vitro affinity ratio of 1:12 (Vaishnavi et al. 2004; see Table 23–1). In contrast, using the same in vivo technique, the dose of milnacipran necessary to inhibit the firing rate of 5-HT neurons by 50% is 5.7 mg/kg (Mongeau et al. 1998). The latter results therefore suggest that milnacipran is much less potent in inhibiting 5-HT reuptake than duloxetine.

Assessments of 5-HT and Norepinephrine Reuptake in Humans

Reuptake of neurotransmitters in humans cannot be assessed as directly as it can in the brains of laboratory animals. Several approaches can, however, provide useful estimates. For instance, 5-HT reuptake inhibition can be estimated using blood platelet uptake of radioactive 5-HT because platelets do not synthesize 5-HT and they have a 5-HTT that is nearly identical to the one present on 5-HT neurons in the brain. And because more than 90% of the 5-HT in blood is in platelets, whole blood can be used to measure 5-HT depletion by a reuptake inhibitor, making assessment simpler. Using this peripheral assay, duloxetine produces a dose-dependent depletion of the 5-HT level that reaches only about 60% with a 60-mg dose, an effect that is significantly inferior to that seen with the TCA clomipramine at a dose of 100 mg (Turcotte et al. 2001). Likewise, milnacipran produces a 64% inhibition of 5-HT uptake with the usual recommended dose of 100 mg (Puozzo et al. 1985). Using a similar assay, SSRIs produce a greater than 80% inhibition with clinically effective doses (Gilmor et al. 2002).

Occupancy of the 5-HTT in the human brain is possible to assess directly using carbon 11

(^{11}C)–labeled ligands of these transporters and positron emission tomography (PET). The minimal effective doses of the SSRIs and venlafaxine for treating depression all result in at least 80% occupancy of the 5-HTT (Meyer et al. 2004). A daily dose of 60 mg, but not 40 mg, of duloxetine produces sustained 80% occupancy (Takano et al. 2006). To our knowledge, milnacipran has not been tested using this approach.

Occupancy of the NET in the human brain is currently not possible because a PET ligand, validated with standard norepinephrine reuptake inhibitors (NRIs), is still lacking. A variety of peripheral measures can, however, be used. In particular, the intravenous tyramine pressor test has produced consistent results. Tyramine penetrates into peripheral norepinephrine terminals through the NET and releases norepinephrine in a calcium-independent manner, thereby transiently elevating the systolic blood pressure. Any drug effectively blocking the NET attenuates this pressor response in a dose-dependent manner. The SSRIs paroxetine and sertraline do not affect this response, whereas the TCAs desipramine, nortriptyline, and clomipramine attenuate it, as is also the case with the selective NRIs maprotiline, reboxetine, and atomoxetine (Blier et al. 2007; Gobbi et al. 2003; Harvey et al. 2000; Slater et al. 2000; Turcotte et al. 2001). Venlafaxine significantly attenuates the tyramine response only at dosages in the 225–375 mg/day range in depressed patients (Aldosary et al. 2007; Debonnel et al. 2007). Duloxetine exerts a clear effect only at 120 mg/day (Vincent et al. 2004), whereas milnacipran, to our knowledge, has not been tested using this model. A variety of other peripheral measures suggest that duloxetine may begin to inhibit norepinephrine reuptake at 60 mg/day (Chalon et al. 2003; Turcotte et al. 2001; Vincent et al. 2004).

Taken together, these results obtained in humans indicate that duloxetine is a potent 5-HT reuptake inhibitor at a dosage of 60 mg/day. The exact degree of norepinephrine reuptake inhibition occurring in humans at 60 mg/day remains uncertain, but at 120 mg/day it reaches a physiologically relevant level without any doubt. A definite answer to the degree of norepinephrine reuptake inhibition produced by duloxetine in the human brain awaits both the availability of a PET ligand for the NET and a comparison with clinically effective doses of selective NRIs such as desipramine. Such experiments will also serve to determine the NET reserve beyond which the overall function of the norepinephrine system is altered, as was determined for the 5-HTT (i.e., 80%; Meyer et al. 2004).

With regard to milnacipran, it appears that it acts preferentially on the norepinephrine reuptake process because it has been easy to find evidence of this action in the brain of laboratory animals even with low doses, whereas 5-HT reuptake inhibition can only be documented with high doses. Robust 5-HT reuptake inhibition (>80%) in humans appears to be achieved only with supratherapeutic doses (i.e., 300–400 mg; Palmier et al. 1989).

MECHANISM OF ACTION

Administration of SNRIs results in a rapid inhibition of reuptake transporters in the brain. However, their therapeutic effect on depression is delayed at least 2 weeks. Extensive electrophysiological and microdialysis studies in laboratory animals have provided consistent results showing a similar delay before SNRIs produce a net enhancement of 5-HT and/or norepinephrine transmission, thereby explaining their therapeutic lag in treating depression (see Blier 2006 for a review). In brief, SNRIs that are potent 5-HT reuptake inhibitors initially suppress the firing of 5-HT neurons through the activation of 5-HT_{1A} autoreceptors on their cell bodies, as a result of 5-HTT inhibition. After 2–3 weeks of sustained administration, the firing rate returns to normal in the presence of sustained reuptake inhibition, due to 5-HT_{1A} autoreceptor desensitization. At this time, there is a net enhancement of 5-HT transmission in the forebrain (Bel and Artigas 1993; Blier and de Montigny 1983; Rueter et al. 1998a, 1998b).

Regarding SNRI inhibition of the NET, the firing rate of norepinephrine neurons is promptly diminished as a result of the activation of the α_2-adrenergic autoreceptors on their cell bodies. After 2–3 weeks of

sustained administration, the firing rate remains attenuated because the cell body α_2-adrenergic autoreceptors do not become desensitized. In contrast, α_2-adrenergic autoreceptors on norepinephrine terminals generally do become desensitized, leading to a net enhancement of norepinephrine transmission in the forebrain in the presence of sustained norepinephrine reuptake inhibition (Invernizzi and Garattini 2004; Rueter et al. 1998a, 1998b; Szabo and Blier 2001).

PHARMACOKINETICS AND DISPOSITION

Absorption and Distribution

Duloxetine is available in an enteric formulation. It is rapidly absorbed after oral administration, and its absorption is not altered by food. Plasma levels are proportional to doses, up to the maximum recommended dose of 60 mg twice daily. It is highly bound to plasma proteins, to an extent of about 90%. Its plasma elimination half-life is approximately 12 hours (Sharma et al. 2000). With repeated administration, duloxetine levels therefore reach a steady-state level after about 3 days.

Milnacipran has low (13%) and nonsaturable plasma protein binding. It is rapidly absorbed after oral administration and has high bioavailability, and its absorption is not affected by food intake. It has no active metabolite, and its elimination half-life is 8 hours. Steady-state levels are thus achieved within 3 days, with no drug accumulation occurring during prolonged dosing, and the drug is cleared from the body within 3 days of treatment cessation. It is eliminated by the kidneys as essentially the parent compound and glucuronide, the inactive glucuronic acid conjugate (Puozzo and Leonard 1996).

Metabolism and Elimination

Duloxetine is extensively metabolized through various pathways (Skinner et al. 2003). Numerous metabolites are found in circulation, none of which is believed to contribute to its therapeutic activity. Duloxetine is metabolized mainly by cytochrome P450 1A2 and 2D6 isoenzymes.

The cytochrome P450 system is not involved in the metabolism of milnacipran (Briley 1998). Its metabolism is mediated mainly through phase II conjugation. Approximately 50%–60% of the drug is recovered in the urine as the parent compound and 20% as its glucuronic acid conjugate, the remainder being excreted mainly as an *N*-dealkyl metabolite and its glucuronic acid conjugate, and in negligible amounts as an *N*-didealkyl metabolite and a hydroxy metabolite (Puozzo et al. 2002).

INDICATIONS AND EFFICACY

Duloxetine has been approved by the FDA for use in treating major depressive disorder, diabetic peripheral neuropathic pain, fibromyalgia, and generalized anxiety disorder; it is also approved in Europe for treating stress urinary incontinence. Additional common off-label uses include other neuropathic pain/chronic pain disorders.

Milnacipran is used to treat major depressive disorder in various countries, although it has not yet received FDA approval for that indication. It was recently approved in the United States for the treatment of fibromyalgia.

Depression

Duloxetine

To date, 12 placebo-controlled studies have evaluated the antidepressant efficacy of duloxetine at dosages of 40–120 mg/day. Many of these had an active drug comparator group. Efficacy was measured by remission, the optimal outcome measure, or by response. Remission can be operationally defined as a score of less than or equal to 7 on the 17-item Hamilton Rating Scale for Depression (Ham-D) or a score of less than or equal to 10 on the Montgomery-Åsberg Depression Rating Scale (MADRS). Response is often defined as a 50% reduction in the MADRS or Ham-D score from baseline to endpoint. These studies and non-placebo-controlled duloxetine trials are summarized in Tables

23–2 and 23–3.

Head-to-head comparisons with SSRIs have yielded mixed results, which appear to be heavily influenced by dosing regimens (see Tables 23–2 and 23–3). In a recent 8-week, placebo-controlled comparison of duloxetine 60 mg/day and escitalopram 10 mg/day, the two drugs produced similar statistically significant improvement versus placebo on the primary efficacy measure of onset of efficacy and similar response and remission rates at endpoint (Nierenberg et al. 2007).

In a recent meta-analysis of six Phase II/III studies that compared duloxetine with two SSRIs (fluoxetine or paroxetine) in outpatients with major depressive disorder, duloxetine 40–120 mg/day was reported to be an effective antidepressant, with an overall efficacy profile equal to that of fluoxetine and paroxetine at 20 mg/day (Thase et al. 2007). For patients stratified as having moderate to severe symptoms, the remission rates with duloxetine were statistically superior to those with the SSRIs (see Table 23–3). Another recent meta-analysis of nine randomized, controlled trials (RCTs) evaluating high doses of duloxetine in patients with severe depression concluded that duloxetine 120 mg/day produced significantly greater baseline-to-endpoint improvement than placebo on several of the 17 Ham-D items (Shelton et al. 2007).

Milnacipran

A meta-analysis of three short-term (4- to 8-week), double-blind, acute efficacy multicenter trials in inpatients and outpatients with moderate to severe depression found that milnacipran exerts a superior antidepressant effect compared with placebo at dosages of 50 and 100 mg twice daily but not at a dosage of 25 mg twice a day (Lecrubier et al. 1996; Macher et al. 1989).

Several studies have compared milnacipran with SSRIs or TCAs in the treatment of depression (Table 23–4). In comparison with the TCA imipramine, milnacipran has been noted to have equal efficacy, but superior tolerability (Puech et al. 1997). A recent meta-analysis concluded that there is insufficient evidence to suggest a difference in response rates between milnacipran and any SSRI: Pooling response rates of the agents revealed an overall response rate of 62.1% for milnacipran and 57.5% for the SSRIs (Papakostas and Fava 2007). To date, no continuation studies (>12 weeks' duration) have been published comparing the efficacy of milnacipran to that of any SSRI. There is no maximal recommended dose of milnacipran, but it is important to mention that the highest daily dose tested so far, 300 mg, was tested in only 41 patients and for only 2 weeks (Ansseau et al. 1991).

[a]Milnacipran was given once daily; this was in contrast to the other studies, in which it was administered on a twice-daily basis.

[b]This is a composite of two positive controlled studies.

Generalized Anxiety Disorder

Three placebo-controlled studies have had positive results showing a therapeutic action with duloxetine in patients with generalized anxiety disorder (Allgulander et al. 2007). Dosing strategies are similar to those used in major depression.

Neuropathic Pain/Chronic Pain

TCAs and SNRIs clearly produce significant relief of physical symptoms such as pain in depression and in a variety of pain syndromes (Stahl et al. 2005). Potentiation of the activity of 5-HT and norepinephrine is believed to result in central pain inhibition through descending modulatory pathways (Sussman 2003).

Duloxetine

Duloxetine exerts a prompt and substantial analgesic effect beyond its antidepressant action (Perahia et al. 2006a). Duloxetine has shown efficacy in the treatment of diabetic peripheral neuropathy in randomized, placebo-controlled trials (Fishbain et al. 2006; Wernicke et al. 2006). Response tends to occur early in therapy and has been associated with significant improvement in functional outcomes

(Armstrong et al. 2007; Pritchett et al. 2007b).

In a recent 8-week study of patients with major depressive disorder and at least moderate pain of unknown etiology, a fixed dosage of duloxetine (60 mg/day) significantly reduced pain measures at endpoint from baseline compared with placebo (Brecht et al. 2007). The mean average pain score at 8 weeks was close to 3 on the Brief Pain Inventory—Short Form, which can be considered a mild level of pain compared with the moderate or higher levels of pain indicated by baseline scores (Brecht et al. 2007). Similarly, elderly patients with depression treated with duloxetine (60 mg/day) for 8 weeks reported significantly greater improvement in back pain scores and amount of time in pain compared with placebo recipients (Raskin et al. 2007).

An RCT of duloxetine 60 mg/day demonstrated greater efficacy than placebo in reducing overall shoulder pain and back pain in depressed patients, as well as time spent with pain (Detke et al. 2002b). Overall pain severity and back pain improved the most. Improvements were assessed with the visual analog scales of pain severity, measuring overall pain, back pain, headaches, shoulder pain, interference with daily activities, and time in pain.

Milnacipran

The capacity of milnacipran to relieve chronic pain has been reported in open trials, but no RCTs have been published to date.

Fibromyalgia

A 12-week RCT of duloxetine 120 mg/day versus placebo in patients with fibromyalgia, some of whom were also diagnosed with depression, found significant improvement in pain scores in duloxetine recipients and greater improvement in tender points compared with placebo recipients (Arnold et al. 2005). Duloxetine 120 mg/day improved fibromyalgia symptoms and pain severity regardless of the extent of the accompanying depressive disorder. The drug has received FDA approval for this indication.

A placebo-controlled study of milnacipran in fibromyalgia patients showed that 37% of the patients treated with 100 mg of milnacipran twice daily experienced a significant reduction in pain intensity of 50% or more compared with 14% of placebo recipients (Vitton et al. 2004). Here, too, milnacipran recently received FDA approval for this indication.

Stress Urinary Incontinence

Duloxetine has been investigated in the treatment of stress urinary incontinence, with 40 mg twice daily being the recommended dosage (Norton et al. 2002). Serotonin and norepinephrine increase excitatory glutamate transmission in the Onuf nucleus in the sacral spinal cord, which facilitates urethral sphincter contraction (Thor 2003). This is presumably the mechanism for the beneficial effect of duloxetine in the treatment of this problem.

The capacity of milnacipran to treat stress urinary incontinence has not been reported to date.

SIDE EFFECTS AND TOXICOLOGY

Duloxetine

In clinical trials to date, the safety and tolerability of duloxetine in the dosage range of 40–120 mg/day have been assessed. In an 8-month study, the most common treatment-emergent adverse events included nausea, dry mouth, vomiting, yawning, and night sweats (Pigott et al. 2007). Most of these emerged early, within the first 8 weeks. Other studies have reported insomnia, somnolence, headaches, ejaculation disorders, diarrhea, constipation, and dizziness as common adverse events with duloxetine (Detke et al. 2002a, 2002b; Khan et al. 2007; Nierenberg et al. 2007).

The rates of nausea with duloxetine appear to be comparable to those found with other SNRIs and with SSRIs. Nausea is transient and usually present at treatment initiation. A starting dosage of 60 mg/day appears to provide the best combination of clinical response and tolerability (Bech et al. 2006; Pritchett et al. 2007a). Clinicians may, however, consider starting at a lower dosage, 30 mg/day, for patients for whom tolerance is a concern. Duloxetine 30 mg/day offers the advantage of a lower rate of nausea as a treatment-emergent adverse event (in one study, 16% vs. 33% with duloxetine 60 mg/day; Dunner et al. 2005). A recent study indicates that the tolerability of duloxetine at an initial dosage of 60 mg/day can be improved if the drug is taken with food, to the point of being comparable to the tolerability at an initial dosage of 30 mg/day (Whitmyer et al. 2007).

Duloxetine has not been associated with weight gain, and in one study it was in fact noted to be associated with a mean 1-kg weight loss (Nierenberg et al. 2007). This decrease was a statistically significant difference compared with the lack of effect that placebo and escitalopram had on weight. Changes in blood pressure and heart rate do not appear to be clinically significant. Pooled data on 735 patients treated with duloxetine 40–120 mg/day showed that 0.7% had a 10-mm Hg increase in systolic or diastolic blood pressure compared with 0.4% of patients receiving placebo. Heart rate was increased by less than 1 beat per minute (Schatzberg 2003).

Rates of sexual dysfunction, including anorgasmia, erectile dysfunction, delayed ejaculation, and decreased libido, appear to be low with duloxetine. Researchers found that after 8 months, categorical outcomes shown on a questionnaire about changes in sexual functioning did not differ significantly between duloxetine and escitalopram groups (Pigott et al. 2007). In clinical practice, however, sexual dysfunction with any drug that potentially inhibits 5-HT reuptake does create some problems in a significant proportion of patients.

Rates of discontinuation due to adverse events have not differed significantly in placebo and active comparator groups in acute or longer-term studies. However, it appears that study subjects who discontinue duloxetine due to adverse events often do so during the early study visits (Nierenberg et al. 2007; Perahia et al. 2008; Pigott et al. 2007), which may suggest poorer initial tolerability.

Milnacipran

Analysis of a database of more than 3,300 patients concluded that the adverse-event profile of milnacipran is comparable to that of the SSRIs, except that with the SSRIs a higher frequency of nausea and anxiety is seen, whereas milnacipran is associated with a higher incidence of dysuria (Puech et al. 1997). Weight gain is uncommon, and sedation may be reported. Data on the occurrence of sexual dysfunction with milnacipran have not been reported, but its prevalence is estimated to be low compared with the prevalence of sexual dysfunction seen with venlafaxine and much lower than that seen with SSRIs (Stahl et al. 2005). The lower incidence of nausea and sexual dysfunction with milnacipran versus SSRIs may be taken as indirect evidence of its lower 5-HT reuptake inhibition potential, these two treatment-emergent adverse events being classically induced by potent 5-HT reuptake inhibitors.

Blood pressure increases with milnacipran are minimal. A 12-week randomized, double-blind study comparing milnacipran dosages of 100 mg/day and 200 mg/day versus fluoxetine 20 mg/day in 289 depressed inpatients found no significant changes in blood pressure in any of the group (Guelfi et al. 1998). Tachycardia, a heart rate of greater than 100 beats per minute, was seen in 0% of patients receiving fluoxetine, 3% of patients receiving milnacipran 100 mg/day, and 6% of patients receiving milnacipran 200 mg/day. A review of more than 4,000 patients treated with milnacipran showed that the mean increase in blood pressure was less than 1 mm Hg and the mean increase in heart rate was 3.6 beats per minute (Puech et al. 1997). Given that an increase of heart rate is a thumbprint of potent norepinephrine reuptake inhibition, this increase is consistent with the capacity of milnacipran to effectively block norepinephrine reuptake. No cardiotoxicity has been reported with overdoses of up

to 2.8 g/day, which is 28 times the recommended daily dose (Montgomery et al. 1996).

Analysis of the long-term safety of milnacipran (in 715 patients receiving milnacipran for >6 months, 189 for >12 months, as reported by Puech et al. 1997) has shown that most adverse events appear within the first 3 months of treatment and that the incidence decreases steadily thereafter. More important, no treatment-emergent adverse events developed during long-term treatment.

DRUG–DRUG INTERACTIONS

Inhibitors of cytochrome P450 1A2, such as ciprofloxacin, increase plasma levels of duloxetine, and their use may require that duloxetine dosages be reduced or that duloxetine use be avoided. When duloxetine is coadministered with a cytochrome P450 2D6 inhibitor of moderate potency, such as bupropion or diphenhydramine, duloxetine levels may increase. Generally, however, such alterations of duloxetine levels are not clinically significant.

Duloxetine does not inhibit or induce the activity of cytochrome P450 1A2, 2C9, or 3A4 systems. It does, however, moderately inhibit the activity of the 2D6 enzyme. If duloxetine is prescribed with an agent metabolized by 2D6, clinicians should use doses that are approximately half those usually recommended for the concomitant medication. Duloxetine does not potentiate the psychotropic effects of ethanol or benzodiazepines.

Because milnacipran is not metabolized by the cytochrome P450 pathways, it does not produce pharmacokinetic drug–drug interactions. However, both milnacipran and duloxetine can have a serious, potentially lethal pharmacodynamic interaction if given concomitantly with a monoamine oxidase inhibitor (MAOI) due to the risk of serotonin syndrome. To avoid this catastrophic outcome, an MAOI must never be administered until at least 5 days after duloxetine or milnacipran has been discontinued. A longer washout period must be respected when switching from an MAOI to an SNRI. A washout period of at least 14 days should elapse before starting any SNRI.

CONCLUSION

At their minimal effective dosages, duloxetine (60 mg/day) and milnacipran (100 mg/day) potently block the reuptake of 5-HT and norepinephrine, respectively. In the case of duloxetine, it is difficult to imagine that increasing the subtherapeutic dosage of 40 mg/day, at which it does not perform as an SSRI, to 60 mg/day would produce marked norepinephrine reuptake inhibition when the in vivo 5-HT–norepinephrine reuptake potency ratio is 1:5. In the case of milnacipran, a 100-mg dose produces suboptimal platelet 5-HT reuptake inhibition. Duloxetine at its maximal recommended dosage (120 mg/day) and milnacipran in its upper therapeutic range (200 mg/day) are dual reuptake inhibitors, but none of the three SNRIs currently available can be considered a balanced serotonin–norepinephrine reuptake inhibitor.

Duloxetine and milnacipran have demonstrated efficacy for the treatment of depression and pain syndromes, with emerging evidence also suggesting a potential role for duloxetine in the treatment of stress urinary incontinence and some anxiety disorders. These medications are generally well tolerated, with most adverse events occurring early in treatment, being mild to moderate in severity, and having a tendency to decrease or disappear with continued treatment.

Either of these two drugs may be used as a first-line treatment for depression because they are not toxic in overdosage and they can be used at therapeutic dosages from treatment initiation onward with minimal side effects. Furthermore, data suggest that treatment with a dual reuptake inhibitor is superior to treatment with an antidepressant with only one mechanism of action, such as an SSRI (Nemeroff et al. 2008; Poirier and Boyer 1999; Thase et al. 2007). Consequently, duloxetine and milnacipran may be useful in patients whose conditions have been resistant to treatment with SSRIs or NRIs, provided that they are used at dosages in the upper end of the therapeutic range.

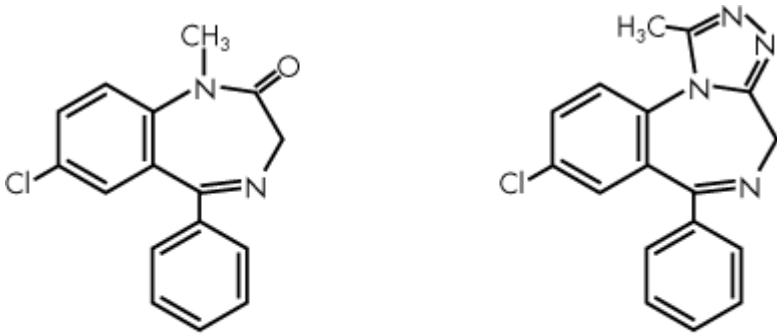
Chapter 24. Benzodiazepines

HISTORY AND DISCOVERY

In spite of adverse publicity and a problematic public image, the most widely prescribed psychiatric medication in the United States over the past several years is not an antidepressant, an atypical antipsychotic, or a mood stabilizer but the benzodiazepine alprazolam, with 31 million prescriptions issued in 2001 (see Stahl 2002).

The first benzodiazepine, chlordiazepoxide (Librium), was patented in 1959. Diazepam was introduced in 1963, and numerous derivatives of this drug have since been introduced into the market. The triazolobenzodiazepine alprazolam was introduced in 1981 and revolutionized the treatment of anxiety disorders when it was shown to be effective in the treatment of panic disorder (Chouinard et al. 1983; D. V. Sheehan et al. 1982). It was the first benzodiazepine to be approved by the U.S. Food and Drug Administration (FDA) for the treatment of panic disorder. Since then, clonazepam, another high-potency benzodiazepine, has also received approval from the FDA for the treatment of panic disorder.

Benzodiazepines were widely prescribed in the 1960s, 1970s, and 1980s for pathological anxiety by psychiatrists, family practitioners, and internists who knew they were effective and relatively safe when compared with prior anxiolytic medications such as the barbiturates and meprobamate. However, since the 1990s, benzodiazepines have increasingly been displaced by the selective serotonin reuptake inhibitors (SSRIs) as the clinician's first choice for the treatment of anxiety disorders (Kramer 1993). The SSRIs are safer and better tolerated than the tricyclic antidepressants and have been shown to be efficacious in a number of different anxiety disorders. In addition, they do not have the dependence, withdrawal, alcohol interaction, and abuse liability of the benzodiazepines. In the United States, benzodiazepine use between 1979 and 1990 decreased from 11.1% to 8.3%. At this time, 35 benzodiazepine products are available worldwide; of these, only 15 are marketed in the United States. Under the Controlled Substances Act (1970), benzodiazepines fall under Schedule IV and are classified as depressants.



Despite these drawbacks, benzodiazepines are often used as an adjunctive treatment with an SSRI or as the primary treatment for the patient with no response or only a partial response to the SSRI. The net result is only a small decline in the recommendation for a benzodiazepine (Uhlenhuth et al. 1999). One user in four uses the benzodiazepine for a year or longer. Among those using it as a hypnotic, 14% reported long-term use (Balter 1991). Rates of use increase with age. Persons older than 65 years account for 27% of all benzodiazepine prescriptions and 38% of all benzodiazepine hypnotics (IMS America 1991). In recent years, there has been a shift to the use of short-half-life benzodiazepines. The use of benzodiazepine hypnotics has remained stable (Woods et al. 1992).

STRUCTURE–ACTIVITY RELATIONS

Currently marketed benzodiazepines are similar in that they have the 1,4-benzodiazepine ring system (see, e.g., Figure 24–1). Modification of this ring system results in benzodiazepines with somewhat different properties. Increasing the electron-attracting ability of the attachment at the R1 position increases its potency. Alprazolam, a triazolobenzodiazepine, is formed by the addition of a

heterocyclic ring that joins the benzodiazepine ring at its 1 and 2 positions (see Figure 24–1) (Sternbach 1982).

PHARMACOKINETICS AND DISPOSITION

Knowledge of benzodiazepine pharmacokinetics helps the clinician choose the most appropriate benzodiazepine for the patient and also guides in its correct use. Benzodiazepines differ in their pharmacokinetic properties, such as absorption, distribution, and elimination (Table 24–1). On the other hand, all benzodiazepines are similar in that to some degree they all exhibit anxiolytic, muscle-relaxant, sedative-hypnotic, and anticonvulsant properties. The belief that one benzodiazepine is primarily anxiolytic while another is primarily hypnotic is not based on scientific evidence (Greenblatt et al. 1983a, 1983b). The preferential selection of a benzodiazepine for one market over another is usually dictated by its pharmacokinetic properties. This, however, is not true for the nonbenzodiazepine hypnotics zolpidem and zaleplon, as they are selective for the benzodiazepine$_1$ (ω$_1$) receptor only.

Rate of Absorption

Benzodiazepines that are rapidly absorbed from the gastrointestinal tract enter and peak in the circulation quickly and have a quicker onset of action than those that are absorbed more slowly. Diazepam and clorazepate are rapidly absorbed and act quickly, chlordiazepoxide and lorazepam have intermediate rates of absorption and onset of action, while prazepam is slowly absorbed and has a slower onset of action.

Gastrointestinal absorption of benzodiazepines is dictated by intrinsic physiochemical properties of the drug and characteristics of the formulation such as particle size (Greenblatt et al. 1983a, 1983b). Benzodiazepine absorption when given intramuscularly is dictated by other factors. For example, chlordiazepoxide and lorazepam when given orally are absorbed at similar rates in the gastrointestinal tract. When given intramuscularly, lorazepam is more reliably, rapidly, and completely absorbed than chlordiazepoxide (Greenblatt et al. 1979, 1982b, 1983a, 1983b).

Lipophilicity

The lipid solubility (lipophilicity) of a benzodiazepine at physiological pH influences the rate at which it crosses the blood–brain barrier by passive diffusion from the circulation, and this, in turn, determines the rapidity of onset of action and intensity of effect (Greenblatt et al. 1983a, 1983b). Highly lipophilic drugs cross the blood–brain barrier rapidly, and although all benzodiazepines are highly lipophilic, they differ in their degree of lipophilicity. As diazepam is more lipophilic than lorazepam or chlordiazepoxide, patients are more likely to experience rapid anxiety reduction and onset of side effects with the former.

Duration of Action

With benzodiazepines, the duration of therapeutic action is determined mainly by the rate and extent of drug distribution rather than by the rate of elimination. Benzodiazepine distribution is largely determined by its lipophilicity. Diazepam, which has a longer half-life than lorazepam, has a shorter duration of clinical action after a single dose. The reason for this is that diazepam, because of its greater lipid solubility, is more extensively distributed to peripheral sites, particularly to fat tissue. Consequently, it is more rapidly moved out of the blood and brain into inactive storage sites and its central nervous system (CNS) effects are more rapidly ended. Conversely, less lipophilic benzodiazepines maintain their effective brain concentrations longer because they are less extensively distributed to the periphery (Greenblatt et al. 1983a, 1983b).

Rate of Elimination

The rate of elimination (elimination half-life) influences the speed and extent of accumulation and the time to reach a steady state. It also influences the time for drug washout after termination of multiple doses. Accumulation is slow and extensive when the half-life is long. When the rate of metabolic removal equals the rate of ingestion, the drug is said to have reached steady state. A useful rule of thumb is that when treatment has been in progress for at least four to five times as long as the elimination half-life, then the accumulation process is more than 90% complete (Greenblatt et al. 1983a, 1983b). When drugs with long elimination half-lives are stopped, they are washed out slowly, and the symptoms recur gradually over a period of days, with less intense or sudden rebound phenomena (Greenblatt et al. 1981, 1982a; Kales et al. 1982). Side effects from long-term treatment

with long-half-life benzodiazepines last longer than with short-half-life benzodiazepines. Because of greater drug accumulation with long-half-life benzodiazepines, frequent drowsiness and sedation are a theoretical concern (Greenblatt et al. 1981). Tolerance to sedation occurs with long-term use, even though the plasma drug level remains the same. However, as a matter of caution, it is prudent to choose a benzodiazepine with a shorter or intermediate half-life for the elderly (Greenblatt et al. 1982c), individuals operating equipment, and those engaged in high-level intellectual tasks.

Biotransformation Pathway

Benzodiazepines are metabolized in the liver by microsomal oxidation or by glucuronide conjugation. The oxidation pathway is influenced by hepatic disease, age, several medical illnesses, and a number of drugs that impair oxidizing capacity, such as cimetidine, estrogens, and the hydrazine monoamine oxidase inhibitors (MAOIs). These factors usually magnify the side effects of the benzodiazepine. Consequently, in the elderly and in individuals with liver disease, benzodiazepines that are conjugated (e.g., temazepam, oxazepam, and lorazepam) are safer than benzodiazepines that are metabolized by oxidation (e.g., diazepam and alprazolam). This is the reason why a patient who is taking alprazolam at a stable dose will report that sedation is potentiated more by the addition of a hydrazine MAOI than by a tricyclic antidepressant.

Dosing: Sustained-Release Formulations

Dosing schedules of benzodiazepines should be dictated by knowledge about the rate of distribution rather than by information about elimination half-life. Patients who require several daily doses often feel as if they are on a roller coaster. They experience peaks of mild sedation followed by troughs of mild anxiety. This can lead to "clock watching" (Herman et al. 1987). Sustained-release formulations of several benzodiazepines have been introduced to correct this problem and are promoted as providing 24 hours of anxiolysis. In our experience, the sustained-release forms of alprazolam, clorazepate, diazepam, and adinazolam have a duration of therapeutic action of approximately 12 hours.

Sustained-release alprazolam has recently been approved by the FDA for use in panic disorder and has been available in 51 countries for some time. The medication in sustained-release alprazolam is enmeshed in a hydroxypropyl–methylcellulose matrix that releases the compound slowly and consistently over several hours so that the patient receives a constant dose of medication for a more extended period than in the immediate-release formulation and a therapeutic benefit lasting 11±4 hours (D. V. Sheehan 1993; D. V. Sheehan et al. 1996).

A number of clinical trials, with a total of 893 patients, have investigated the efficacy and safety of sustained-release alprazolam in the treatment of panic disorder (Alexander 1993; Pecknold et al. 1993, 1994; Schweizer 1993; Stahl 1993). The results of these studies suggest that sustained-release alprazolam, administered once in the morning, is superior to placebo and is equal to comparable doses of alprazolam in its compressed or immediate-release tablet form administered in four divided doses. When given in fixed doses twice daily, sustained-release alprazolam was found to be superior to placebo and also appeared to cause fewer CNS side effects than with single-dose administration. Given in a single dose at bedtime, it was not more effective than placebo.

These studies do not answer practical clinical questions such as how to adjust dosing during a switch from the compressed-tablet to the extended-release formulation of a benzodiazepine. A methodology for switching patients from a stable maintenance dose of the compressed-tablet formulation of alprazolam to the extended-release formulation was described by D. V. Sheehan et al. (1996). This methodology, developed in connection with a 9-week open-label crossover study, relies on the use of a patient diary in which the patient records hourly anxiolytic benefit on a 0–10 scale as well as any side effects. During the first week, while patients were still taking the compressed-tablet formulation, they were instructed to keep hourly recordings of the degree of anxiolytic effect and any side effects

they experienced after the first morning dose. They were further instructed to wait until they saw a dip in efficacy (evidence of a loss of therapeutic action documented in their diary records) before taking a second dose. This made it possible to establish the average time it took for the first dose to lose therapeutic effect, which was labeled as the endpoint of duration of therapeutic action (DOA). Once the DOA of an effective dose was established, efforts were directed to adjusting the distribution of doses to provide optimal control. At the end of 3 weeks, all patients were switched to an equivalent dose of sustained-release alprazolam in 0.5- or 1.0-mg tablets. At the switch, the total number of milligrams of the compressed-tablet formulation of alprazolam taken before 5:00 P.M. was converted into the morning dose of sustained-release alprazolam, and the total number of milligrams of the compressed-tablet formulation taken after 5:00 P.M. was converted into the evening dose of sustained-release alprazolam.

With this methodology, equivalent efficacy for the compressed-tablet and sustained-release formulations was found on weekly ratings of anxiety. At the end of the study (week 9), diary records provided evidence of the considerably longer mean duration of therapeutic action of the sustained-release formulation compared with the compressed-tablet formulation: 11.3±4.2 hours (range = 3–24 hours) versus 5.1±1.7 hours (range = 3–11 hours). The major advantage of the sustained-release form is the convenience of less frequent dosing. Since most (81%) of the patients in the described study (D. V. Sheehan et al. 1996) required only once- or twice-daily dosing, compliance is likely to be higher.

When doses were adjusted with patient input to achieve a smooth therapeutic effect over 24 hours (as reflected in symptom scale scores), the majority reported the best effects with two-thirds of the total daily dose in the morning (8:00 A.M.) and one-third of the total daily dose in the evening (7:00 P.M.) (D. V. Sheehan et al. 1996, 2007). While this may seem odd, there are several explanations for this phenomenon. One explanation is "the second-dose effect in pharmacokinetics" (DeVane and Liston 2001). The effect of a second dose of a medication is always more intense and lasts longer than the effect of the first dose. However, this relative increase in effect diminishes with subsequent doses. When dosing is repeated in response to the observed effect, the second-dose effect occurs regardless of the half-life of the drug. Another explanation is that the individual sleeps during much of the time when the second dose of the day (taken in the evening) is active. During sleep, the individual is less aware of feedback indicating a need for full anxiolytic effect. Yet another explanation is that the anxious patient reports more anxiety in the morning. To better control this early-day anxiety, the patient feels a need for a slightly higher dose at that time. The study by D. V. Sheehan et al. (1996) reaffirms that the half-life of a benzodiazepine does not predict its duration of action. It also provides the clinician with a methodology for switching patients on a regular compressed-tablet formulation of a benzodiazepine to the extended-release formulation of that benzodiazepine (D. V. Sheehan et al. 1996, 2007).

MECHANISM OF ACTION

Benzodiazepines produce anxiolysis by their effect on the γ-aminobutyric acid (GABA)–benzodiazepine receptor complex. GABA is synthesized from glutamic acid, which is also the most abundant free amino acid in the CNS. Like serotonin, norepinephrine, and dopamine neurons, the presynaptic GABA neuron has a reuptake pump that transports GABA from the synapse for storage or destruction by GABA transaminase. GABA has two target receptors, $GABA_A$ and $GABA_B$. The chloride ion channel is controlled by $GABA_A$. A number of nearby receptors have the ability to allosterically modulate the $GABA_A$ receptor. These include receptors for benzodiazepines, for nonbenzodiazepine sedatives like zolpidem and zaleplon, for barbiturates, for alcohol, for neuroactive steroids, and for the proconvulsant picrotoxin. The $GABA_B$ receptor has two dissimilar subunits that comprise the functional receptor ($GABA_{B1}$ and $GABA_{B2}$). Six $GABA_{B1}$ isoforms (1a through 1f) have been reported (Dawson et al. 2005). The $GABA_B$ receptor is not allosterically modulated by benzodiazepines but is known to bind

to the muscle relaxant baclofen.

Four distinct pharmacological properties have been described for the benzodiazepine receptor: anxiolytic, hypnotic, anticonvulsant, and muscle relaxation effects. Anxiolytic and sedative-hypnotic actions are mainly mediated by the ω_1 receptor and muscle relaxation through the benzodiazepine$_2$ (ω_2) receptor. Most benzodiazepines interact with both these receptor subtypes. The benzodiazepine$_3$ (ω_3) receptor is found mostly outside the CNS, and its role is unclear at this time. Typically, when GABA occupies the $GABA_A$ receptor site, the chloride channel is opened up a little, and this effect is inhibitory. If at the same time a benzodiazepine binds to the nearby benzodiazepine receptor, the $GABA_A$ receptor is allosterically modulated, and GABA exerts a greater effect on the chloride channel and conductance. Although GABA works alone at the GABA receptor, it works better in the presence of a benzodiazepine. The benzodiazepine, on the other hand, in the absence of GABA cannot influence the chloride channel by itself.

The $GABA_A$ receptor–chloride ion channel complex has a transmembrane pentameric structure. There are five subunits selected from eight polypeptide classes: α, β, γ, δ, ε, π, ρ, and τ. Several of these classes have subunits that have been characterized (6 α, 3 β, 3 γ, and 2 δ variants). As a consequence, there is the potential for the existence of a large number of receptor isoforms. The coassembly of an α, a β, and a γ subunit produces a high-affinity benzodiazepine binding site. Benzodiazepines also potentiate combinations of α and γ, or β and γ, subunits. On the other hand, benzodiazepines do not potentiate combinations of α and β subunits even though they are functional $GABA_A$ receptors. The α subunit seems to dictate the pharmacology of the benzodiazepine receptor site. Combinations with α_1 have different pharmacology compared with combinations with α_2 or other alpha variants. Sedation and anticonvulsant activity are mediated by the α_1 subunit and anxiolysis by the α_2 subunit (Low et al. 2000; Mohler et al. 2002). It has been suggested that benzodiazepine-induced hyperphagia is mediated by the α_2 and α_3 subtypes (Cooper 2005).

THERAPEUTIC USES

Because of their multiple pharmacological actions, benzodiazepines have been found useful in many areas of medical practice, such as induction of anesthesia, use as a muscle relaxant, and control of seizures. It is beyond the scope of this chapter to elaborate on these uses.

In psychiatry, benzodiazepines are used to control anxiety, to treat insomnia, and to acutely manage agitation and withdrawal syndromes. Surprisingly, in the treatment of anxiety disorders, benzodiazepines have a greater impact in some disorders than others. In panic disorder, they have a significant impact on all dimensions of the illness, with the exception of depression. Alprazolam, for example, has been shown to be effective in panic disorder at a mean dosage of 5.7 mg/day (range = 1–10 mg/day) (Ballenger et al. 1988; Chouinard et al. 1982; Cross National Collaborative Panic Study 1992; D. V. Sheehan et al. 1982, 1984, 1993). Rapid improvement can be observed within the first week in terms of decreased panic attacks, phobic fears and avoidance, anticipatory anxiety, and disability. These benefits have been shown to persist during a follow-up period of 8 months (Schweizer et al. 1993). Efficacy has also been shown for lorazepam (Rickels and Schweizer 1986) and clonazepam (Pollack et al. 1993; Tesar et al. 1991). In the latter study, clonazepam 2.5 mg/day was as effective and well tolerated as alprazolam 5.3 mg/day.

Despite the well-documented efficacy of benzodiazepines in panic disorder, they have been displaced in clinical practice by the SSRIs. However, it is common practice to initiate treatment with both classes of drug simultaneously and then withdraw the benzodiazepine after 6 weeks. The benefits and practicality of this approach to treating panic disorder have been reinforced by the findings from a 12-week study (Goddard et al. 2001) in which patients with panic disorder were treated with open-label sertraline and double-blind clonazepam or placebo. After 4 weeks of combination treatment, the adjunct medication (clonazepam or placebo) was tapered over 3 weeks and then

discontinued. All patients received sertraline monotherapy for the last 4 weeks of the study. The group randomized to sertraline and clonazepam had fewer dropouts (25% vs. 38%) and separated as early as week 1 from the sertraline–placebo group on the Panic Disorder Severity Scale (PDSS). These findings have been further reaffirmed by a recent double-blind, placebo-controlled study (Goddard et al. 2008) in which patients were randomly assigned to flexible-dose treatment with either sertraline plus placebo or sertraline plus extended-release alprazolam for 4 weeks, followed by a 4-week taper from the benzodiazepine, followed by 4 weeks on sertraline alone. Onset of benefit was faster in the initial weeks on the SSRI–benzodiazepine combination, and the dropout rate was lower in this group, but withdrawal symptoms were significantly higher in the benzodiazepine–SSRI group. At the end of 12 weeks, there was no difference in efficacy between the two groups (Goddard et al. 2008). The American Psychiatric Association (1998) guidelines for the treatment of panic disorder recommending SSRI monotherapy as the treatment of first choice has failed to achieve traction, since more than two-thirds of the SSRI prescriptions were accompanied by a concomitant benzodiazepine. The above studies by Goddard et al. (2008) lend justification to the rationale for using the combination treatment more frequently and blessing it as a reasonable alternative first-line treatment for many patients with panic disorder.

Three double-blind studies have shown efficacy for benzodiazepines in the treatment of social phobia. In the first study (Gelernter et al. 1991), alprazolam demonstrated only limited efficacy relative to other treatments. At week 12 (end of study), 69% of phenelzine-, 38% of alprazolam-, 24% of cognitive-behavioral-, and 20% of placebo-treated patients had responded. In the second study (Davidson et al. 1993), at the end of 10 weeks of treatment, 78% of social phobia patients treated with clonazepam, compared with only 20% of those treated with placebo, responded. The mean dosage of clonazepam at endpoint was 2.4 mg/day. Bromazepam, a benzodiazepine not available in the United States, was found to be effective in a 12-week double-blind, placebo-controlled study of social phobia at a mean dosage of 21 mg/day, but it took 8 weeks for bromazepam to separate from placebo (Versiani et al. 1997).

In two parallel and concurrent studies (D. V. Sheehan et al. 1990a, 1990b), we demonstrated that the sustained-release formulation of the benzodiazepine adinazolam was effective in panic disorder and generalized anxiety disorder (GAD). However, the dose of adinazolam needed to treat GAD effectively was higher than the dose needed to treat panic disorder. Endpoint scores on the Hamilton Anxiety Scale (Ham-A) were lower (better) in the patients with panic disorder, even though the mean effective dose of adinazolam was lower than in the GAD patients. This suggests that, contrary to prior assumptions, benzodiazepines in general, and adinazolam in particular, are less effective in GAD than in panic disorder. This has some support from findings in a double-blind, placebo-controlled study (Rickels et al. 1993) showing that the tricyclic antidepressant imipramine was better than diazepam in the treatment of nondepressed GAD patients over 8 weeks. Imipramine showed a trend to be significantly better on the primary outcome measure scale (Ham-A) and was statistically superior to diazepam on the Psychic Anxiety factor of the Ham-A. Psychic anxiety includes the items of worry, anxious mood, tension, fears, and concentration problems. Diazepam and imipramine had identical endpoint Ham-A Somatic Anxiety factor scores, suggesting that they are equally effective against the somatic anxiety symptoms in GAD. This suggests that imipramine is a better "anti-worry" medication than the benzodiazepine. Patients treated with diazepam had an earlier response than those taking imipramine.

Generally, benzodiazepines are thought to be ineffective in the treatment of obsessive-compulsive disorder (OCD). In a small crossover study, clonazepam was reported as effective in treating OCD (Hewlett et al. 1992).

The strongest evidence for effective pharmacotherapy in posttraumatic stress disorder (PTSD) is with SSRIs. A meta-analysis of six studies showed a correlation between greater serotonergic activity and

higher effect size (Penava et al. 1996–1997). Another meta-analysis of medications in treating PTSD found effect sizes of 0.49 and 1.38 for benzodiazepines and SSRIs, respectively (Van Etten and Taylor 1998). In a study of 13 trauma survivors treated prophylactically within 2–18 days of their trauma with lorazepam or clonazepam for 6 months, the subjects did not do any better than a matched untreated group in terms of PTSD symptoms at the 6-month evaluation (Gelpin et al. 1996).

Benzodiazepines have potential for benefit in the acute management of mania, as they can rapidly induce sleep with earlier resolution of the mania and allow for lower doses of antipsychotics in the acute phase (Nowlin-Finch et al. 1994). Antimanic effects have been described for clonazepam. In a double-blind, crossover study, clonazepam was more efficacious than lithium and also had a faster onset of action (Chouinard et al. 1983). It has been reported that clonazepam is more effective in acute mania than lorazepam (Bradwejn et al. 1990).

Intramuscular clonazepam has been compared with intramuscular haloperidol in the management of acute psychotic agitation. Clonazepam use reduced agitation, but haloperidol use had a more rapid onset (Chouinard et al. 1993). Individuals with schizophrenia have high levels of anxiety and frequently experience panic attacks. High-potency benzodiazepines as adjunctive therapy have been shown to benefit schizophrenic patients, with or without panic attacks, in the short term. But long-term use is problematic given this population's poor adherence to therapeutic regimens, their propensity to substance abuse and dependence, and the dangers of benzodiazepine dependence and withdrawal syndromes with chronic use (Wolkowitz and Pickar 1991). Overall, it appears that benzodiazepines have a role in the acute management of agitation, and their use can reduce the need for or the dose of antipsychotics used.

SIDE EFFECTS AND TOXICOLOGY

Benzodiazepines are among the safest of drugs, but unwanted effects do occur. The first 1,4-benzodiazepines, such as diazepam and flurazepam, had slow rates of elimination and low receptor-binding affinities. Their main side effect was excessive daytime sleepiness. The late 1970s saw the introduction of the 1,4-benzodiazepines flunitrazepam and lorazepam, which had shorter half-lives and were more potent. These drugs were associated with enhanced efficacy but also with more rapid development of tolerance and significant withdrawal problems. The triazolobenzodiazepines were introduced in the 1980s and were even more potent and had even shorter half-lives. They have also been found to be associated with amnesia, daytime anxiety, early-morning insomnia, and withdrawal problems such as rebound insomnia, anxiety, and seizures (Noyes et al. 1986).

Sedation and drowsiness are common, occurring in 4%–9% of patients taking benzodiazepines. Ataxia occurs in up to 2%. The drowsiness tends to disappear with time or a reduction in dose (Greenblatt et al. 1982b; R. R. Miller 1973; Svenson and Hamilton 1966). Several lines of investigation suggest that benzodiazepines may impair psychomotor performance. Most benzodiazepines, shortly after administration, at their peak concentration cause anterograde amnesia (Lister et al. 1988). These effects are dependent on potency and route of administration. For example, with a low-potency drug such as diazepam, the risk of amnesia is highest with intravenous, less with intramuscular, and rare with oral administration (Bixler et al. 1979). It has been shown that when given orally, lorazepam and flunitrazepam cause more amnesia than diazepam and flurazepam (Magbagbeola 1974). Triazolam, a very potent triazolobenzodiazepine, is reported to cause significantly more memory impairment than other hypnotics such as flurazepam and temazepam (Greenblatt et al. 1989; Ogura et al. 1980; Roth et al. 1980; Scharf et al. 1988). Overall, this memory impairment does appear to be independent of the degree of sedation produced by the drug (Scharf et al. 1988). Also of great significance is that benzodiazepine-treated subjects are often unaware or underestimate the extent of their memory impairment (Roach and Griffiths 1985, 1987).

Hyperexcitability phenomena such as early-morning awakening and rebound anxiety and nervousness are more likely with the short-half-life, high-potency benzodiazepines such as triazolam, alprazolam, lorazepam, and brotizolam (Kales et al. 1983, 1986, 1987; Vela-Bueno et al. 1983). Treatment-emergent hostility (Rosenbaum et al. 1984) may be seen in up to 10% of patients being treated with benzodiazepines. This is most likely to happen early in treatment, is unrelated to pretreatment impulsivity, and has been reported with all benzodiazepines with the exception of oxazepam. Treatment-emergent mania has been reported with alprazolam (Goodman and Charney 1987; Pecknold and Fleury 1986; Strahan et al. 1985). Depression may also emerge with treatment (Pollack et al. 1986). We have seen increased dreaming in some patients, and there are case reports of reversible hepatitis (Judd et al. 1986), ejaculatory inhibition (Munjack and Crocker 1986), and inhibition of female orgasm (Sangal 1985).

Since the 1960s, benzodiazepines have been known to produce anterograde amnesia. Initially, it was believed that this effect happened only with intravenous use. But now the effect is well documented, even with oral dosing (Lister 1985). It is likely that the amnestic effects are produced by interference with the transfer of information from very-short-term memory to long-term memory storage areas. The deficit is therefore one of disrupted consolidation and not impairment of memory retrieval. The degree of amnesia can range from minimal inability to retain isolated pieces of information to total inability to recall any activities that occurred during a specific period. Whether some benzodiazepines are more likely than others to produce amnesia remains an unresolved question.

Triazolam 0.5 mg has been compared to 30 mg of temazepam on immediate and delayed recall. In tests of delayed recall, triazolam consistently caused anterograde amnesia. No effects were found in immediate recall in both drugs (Scharf et al. 1988). Retrograde facilitation was better with triazolam than with temazepam. Triazolam, lorazepam, and alprazolam are the compounds that show the most amnestic potential. Compared with temazepam and clorazepate, they also tend to be those with the greater benzodiazepine receptor affinities, lower volumes of distribution, and less lipophilicity (Nutt et al. 1989). It is not clear if chronic dosing with benzodiazepines aggravates the problem. One study comparing lorazepam and alprazolam suggests memory impairment dissipates beyond the single-dose administration period (Kumar et al. 1987). Another area of concern is that the long-term use of benzodiazepines may lead to cognitive and other impairments that persist long after the drug has been discontinued. Abnormal computed tomography scans were reported in long-term users of benzodiazepines in one study (Lader et al. 1984) but not in others (Poser et al. 1983; Rickels 1985). Busto et al. (2000) found no difference in the computed tomography scans of brains of patients taking benzodiazepines compared with control subjects. Paulus et al. (2005) reported a dose-dependent decrease of activation in bilateral amygdala and insula by lorazepam during emotion processing. No other positron emission tomography or functional magnetic resonance imaging studies that might inform this question are yet available. Long-term benzodiazepine users have been compared with controls and found to have cognitive impairments that reversed on reexamination after taper (Golombok et al. 1988; Lucki et al. 1986; Rickels et al. 1999; Sakol and Power 1988). Another study found that after long-term use, if the benzodiazepine is stopped, there was only partial recovery even after 6 months (Tata et al. 1994).

DRUG–DRUG INTERACTIONS

Antacids slow benzodiazepine absorption, as aluminum delays gastric emptying (Greenblatt et al. 1983a, 1983b). An acid medium is needed for conversion of clorazepate to desmethyldiazepam, the active metabolite, which is then absorbed (Shader et al. 1978).

In the liver, benzodiazepines are metabolized by oxidation, reduction, or conjugation. Alprazolam, diazepam, clorazepate, prazepam, chlordiazepoxide, bromazepam, and halazepam are metabolized by oxidation; nitrazepam by reduction; and lorazepam, oxazepam, and temazepam by conjugation. Inhibitors of the oxidase system prolong the half-life of benzodiazepines that are metabolized by this

system. This accentuates the side effects, notably the sedation, ataxia, slurred speech, and imbalance. A decrease in dosage may solve this problem, or a switch to a benzodiazepine that is metabolized by conjugation may be needed. MAOIs, cimetidine (Greenblatt et al. 1984), and oral contraceptives inhibit the oxidative system. There is a decline in this system with age or liver disease. In the elderly, there is a 50% decrease in clearance, with a four- to ninefold increase in half-life and a two- to fourfold increase in the volume of distribution (Peppers 1996). Due to the decreased clearance of lorazepam, lower doses of the benzodiazepine are recommended in patients taking valproate or probenecid. Phenytoin and barbiturates (Scott et al. 1983) cause hepatic enzyme induction and reduce benzodiazepine half-life. Heparinized patients (Routledge et al. 1980) should have partial thromboplastin time (PTT) monitored more closely, as PTT is prolonged by benzodiazepines. Benzodiazepines increase digoxin levels (Castillo-Ferrando et al. 1980; Tollefson et al. 1984), increasing the chance of digoxin toxicity. As antidepressants like fluoxetine or nefazodone and protease inhibitors like indinavir sulfate inhibit the cytochrome P450 enzyme 3A4, they inhibit the metabolism of triazolobenzodiazepines such as midazolam, alprazolam, and triazolam. Inhibition of the gag reflex can occur with benzodiazepine administration (Nutt et al. 1989), increasing the risk for aspiration in patients with nausea and vomiting.

CLINICAL ISSUES

Despite decades of research, the optimal extent and duration of appropriate benzodiazepine use in the treatment of anxiety and related disorders remain unresolved. This is primarily because of concerns expressed by prescribers, regulators, and the public about issues such as tolerance, dependence, and abuse liability of this class of medication.

Tolerance

In a study of persistent users of alprazolam and lorazepam, Romach et al. (1995) found that most were not abusing these benzodiazepines, nor were they addicted to them; rather, they were using them appropriately for a chronic disorder and at a constant or a decreasing dose. Soumerai et al. (2003) found a lack of relationship between long-term use of benzodiazepines and escalation to high doses in 2,440 long-term (at least 2 years) users of benzodiazepines and that escalation to a high dose was very rare. Superior results with benzodiazepines are only achieved long term by careful attention to dose adjustment guidelines. The benefits are usually apparent within 2–3 weeks of starting the drug. At this stage, patients often report that the medication is no longer working as well as it did initially. Concurrently, the side effects have also subsided, because of tolerance. If the dose is adjusted up to the next level, the patient again usually gets benefit and continues to do well for another 4–6 weeks. At this stage, tolerance may yet again develop, with the patient losing some benefit and side effects. At this point, adjustment of the dose upward results in benefit again. Physicians may be concerned that there will be no end to this upward adjustment of the dose. However, with effective benzodiazepine therapy, there is a limit to the number of such plateaus that patients go through before reaching their final effective dose. Typically, this dose is reached by the second or third plateau, usually around week 10 or 12. Failure to identify and take appropriate action during these early troughs of partial tolerance in the initial weeks of treatment is common. Sometimes, patients will unilaterally increase the dosage to achieve benefit. The clinician should not take this to be evidence of addictive behavior. Benzodiazepines differ with regard to the degree and timeline for the development of tolerance. As a general rule, long-half-life benzodiazepines such as flurazepam, quazepam, diazepam, and clonazepam tend to be effective for a month or longer before tolerance is exhibited. On the other hand, short-half-life benzodiazepines such as triazolam, alprazolam, temazepam, and lorazepam lose some of their initial efficacy sooner, sometimes in just over a week (Bayer et al. 1986; Bixler et al. 1978; Kales et al. 1986, 1987).

One milligram of alprazolam is approximately equivalent to 0.7 milligrams of clonazepam, to 10 milligrams of diazepam, and to 1 milligram of lorazepam. The cross-tolerance between the

benzodiazepines, although good, is not perfect, and it is preferable not to switch patients abruptly from one benzodiazepine to another.

Withdrawal

A withdrawal syndrome is defined as a predictable constellation of signs and symptoms involving altered CNS activity (e.g., tremor, convulsions, or delirium) after the abrupt discontinuation of, or rapid decrease in, dosing of the drug (Rinaldi et al. 1988). Typically, a withdrawal syndrome from short-half-life benzodiazepines will intensify by the second day, will usually have peaked by day 5, and will begin to decrease and taper off by day 10. After 2 weeks, withdrawal symptoms have usually become minimal or absent. Drug factors associated with withdrawal symptoms include length of use, dose, potency, and rate of discontinuation. Psychic, physical, and perceptual symptoms can be observed during withdrawal. The most common are anxiety, restlessness, irritability, insomnia, agitation, muscle tension, weakness, aches and pains, blurred vision, and racing heart, in that order (O'Brien 2005). Nausea, sweating, runny nose, hypersensitivity to stimuli, and tremor are less frequent. Severe withdrawal symptoms, such as psychosis, seizures, hallucinations, paranoid delusions, and persistent tinnitus, are relatively rare and are more likely to occur in abrupt withdrawal from high doses of high-potency benzodiazepines and in the elderly (American Psychiatric Association 1990; Lader 1990; Petturson and Lader 1991).

The minimum duration of use after which clinically significant withdrawal symptoms can be expected has not been definitively determined. At the end of any course of treatment with therapeutic doses and of duration greater than 3–6 weeks, withdrawal of the benzodiazepine should be done as a slow taper. This reduces the risk of unpleasant withdrawal symptoms and the danger of withdrawal seizures and minimizes rebound reactivation of the underlying anxiety disorder (Fontaine et al. 1984; Pecknold et al. 1988; Power et al. 1985).

We recommend that alprazolam or clonazepam not be withdrawn at a rate faster than 0.5 mg every 2–3 weeks. If the drug is tapered at this rate, it is very unlikely that you will see a withdrawal seizure. In a patient taking either drug at a dosage of 6 mg/day, it may take a few months to complete taper on such a slow withdrawal schedule. However, there are no clinical reasons to taper more rapidly. All pharmaceutical companies manufacturing benzodiazepines and the FDA should encourage physicians to withdraw patients from all benzodiazepines at much slower rates than those currently recommended in order to prevent these complications. The recommended rate of withdrawal from alprazolam, for example, is not faster than 0.5 mg every 3 days. In our opinion this rate is too fast. All patients should be advised about the dangers of abruptly stopping the medication, and this should be documented. A systematic review of the literature on this topic in the Cochrane Database recommended slow withdrawal over 10 weeks (Denis et al. 2006).

A number of factors are thought to influence the severity of the withdrawal syndrome. Withdrawal is more difficult with the use of short-half-life drugs, higher doses, long duration of use, rapid tapering, a diagnosis of panic disorder, and certain personality traits (Rickels et al. 1988, 1990; Schweizer et al. 1990). Eighteen percent of patients taking diazepam for 14–22 weeks had withdrawal symptoms, and 43% had withdrawal symptoms after 8 months of use (Rickels et al. 1983). Thirty-five percent of patients taking alprazolam (2–10 mg/day) for 8 weeks had withdrawal symptoms (Pecknold 1993; Pecknold et al. 1993). The first 50% of taper can be done fairly quickly over a 2- to 4-week period. It may be helpful to stay at this dose for several weeks or even a few months before proceeding with the remaining 50% taper at a very slow rate. Early dropouts from taper were found to score higher on the Dependence factor of the Minnesota Multiphasic Personality Inventory compared with late-taper dropouts and those who tapered successfully (Schweizer et al. 1998). In a 3-year follow-up of patients who had participated in a benzodiazepine taper program, it was found that of those who tapered successfully, 73% remained benzodiazepine free. Among those who were able to reduce intake by 50%, only 39% were benzodiazepine free at the end of 3 years. In the group that could not

tolerate taper at all, only 14% were benzodiazepine free (Rickels et al. 1991).

A variety of medications have been tried as adjuncts to facilitate taper. Propranolol (Tyrer et al. 1981), progesterone (Schweizer et al. 1995), and dothiepin (Tyrer et al. 1996) were not better than placebo. Buspirone (Lader and Olajide 1987; Rickels 1988; Schweizer and Rickels 1986) was ineffective in patients who had used benzodiazepines for a year or longer but was of some benefit in those who had used lorazepam for a period of 3 months or less (Pancheri et al. 1995). Some benefit for carbamazepine at dosages of 200 to 600 mg/day has been reported (Klein et al. 1986; Neppe and Sindorf 1991; Schweizer et al. 1991; Swantek et al. 1991).

Addiction Potential

In our zeal to heal an anxiety disorder, are we creating a population of addicts? There is much misinformation and concern generated because terms like *addiction* are used without precise definition and pejoratively. Terms such as *addiction, physical dependency,* and *withdrawal syndrome* are often used interchangeably. There is a presumption that a medicine's being associated with a withdrawal syndrome is evidence that the medicine is addicting. Some clinicians believe that benzodiazepines that require frequent dosing during the day are more addicting than those that require less frequent dosing. In fact, frequency of dosing is a function of the duration of therapeutic action of the drug rather than of any innate addiction potential of the drug.

DSM-IV-TR (American Psychiatric Association 2000) defines *substance (drug) dependence* as a maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by three (or more) of the criteria shown in Table 24–2 occurring at any time in the same 12-month period. *Addiction,* in contrast, is defined as a chronic disorder associated with compulsive use of a drug, resulting in physical, psychological, or social harm to the user and continued use despite that harm (Rinaldi et al. 1988). Addiction involves both intense drug-seeking behavior and difficulty in stopping the drug use. If these criteria are used, benzodiazepines are not addictive drugs. *Physical dependence* is different from addiction and is defined as a physiological state of adaptation to a drug, with the development of tolerance to the drug's effects and the emergence of a withdrawal syndrome during prolonged abstinence. During withdrawal after chronic use, biochemical, physiological, or behavioral problems may be triggered. When used on a regular schedule, benzodiazepines are associated with physical dependence, as opposed to drug dependence or DSM-IV-TR "substance dependence," and have a withdrawal syndrome. In *psychological dependence* (Rinaldi et al. 1988), there is a state of emotional craving either to experience the drug's positive effect or to avoid the negative effects associated with its absence. This can lead to compulsive drug-seeking behavior.

TABLE 24–2. DSM-IV-TR criteria for substance dependence

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period:

(1) tolerance, as defined by either of the following:

(a) a need for markedly increased amounts of the substance to achieve intoxication or desired effect

(b) markedly diminished effect with continued use of the same amount of the substance

(2) withdrawal, as manifested by either of the following:

(a) the characteristic withdrawal syndrome for the substance (refer to criteria A and B of the criteria sets for withdrawal from the specific substances)

(b) the same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms

(3) the substance is often taken in larger amounts or over a longer period than was intended

(4) there is a persistent desire or unsuccessful efforts to cut down or control substance use

(5) a great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors or driving long distances), use the substance (e.g., chain-smoking), or recover from its effects

(6) important social, occupational, or recreational activities are given up or reduced because of substance use

(7) the substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., current cocaine use despite recognition of cocaine-induced depression, or continued drinking despite recognition that an ulcer was made worse by alcohol consumption)

Abuse

Studies of abuse use four criteria for benzodiazepine abuse. A benzodiazepine is being abused if it is taken 1) to get high, 2) to promote psychological regression, 3) at doses higher than prescribed, and 4) after the medical indication has passed (Dietch 1983). On the basis of this definition, the data suggest that the incidence of benzodiazepine abuse in clinical practice is low.

A U.S. national health survey in 1979 found that 1.6% of subjects studied used benzodiazepines regularly for at least 1 year (Mellinger et al. 1984). In another study of anxiolytic medication users in the United States, 15% used these drugs daily for more than 1 year (Balter et al. 1984). In a London general practice, 1.6% used benzodiazepines for more than 1 year (Salinsky and Dore 1987). In an Australian general practice study, 10% of first-time benzodiazepine users were still using them with no dose increase after 6 months (Mant et al. 1988). The incidence of benzodiazepine dependence in the therapeutic setting (among those for whom the drug is medically correctly prescribed) was estimated to be 1 case in 50 million patient-months (Marks 1978). Of these cases, 92% were associated with alcohol or other drugs of abuse. This estimate is probably on the low side since it is based on the number of published cases of dependence from 1961 to 1977. There is a positive correlation between benzodiazepine use and psychiatric morbidity (Fichter et al. 1989; Pakesch et al. 1989; Salinsky and Dore 1987; Schwartz and Blank 1991). "Benzodiazepine dependence" was diagnosed in only 150 cases (0.5%) of 33,000 consecutive admissions between 1974 and 1983 at a German psychiatric hospital. In contrast, 18.5% of admissions in 1984 ("quarterly incidence") were found to involve long-term users of benzodiazepines (Laux and Konig 1987).

In Basel, Switzerland, with a catchment area of 300,000 people, physicians were surveyed on the prevalence of benzodiazepine abuse in their patients. Only 31 patients were identified—a prevalence of 0.01%, or 1 in 10,000. An additional 88 polysubstance abusers were identified (Ladewig and Grossenbacher 1988). In a small prospective study involving 71 outpatients treated with benzodiazepines for a diagnosis of major depression or an anxiety disorder, no evidence of benzodiazepine abuse was found. Five patients (7%) with a diagnosis of major depression misused benzodiazepines (Garvey and Tollefson 1986). Another study prospectively followed 99 anxiety disorder patients with a history of alcohol abuse and dependence and 244 without such a history. Over the 12 months of the study, only minor differences in the use of benzodiazepines were noted for the groups. The authors concluded that in patients with an anxiety disorder, the presence or absence of a history of alcohol use disorder was not a strong predictor of future abuse (Mueller et al. 1996). In a random sample of all psychiatric hospitalizations over 15 years (1967–1983) in Sweden (*n* = 32,679), Allgulander (1989) found only 38 admissions for substance dependence on sedative hypnotics. Twenty-one of the 38 had polysubstance abuse, and 17 had sedative-hypnotic abuse. In another study of all medical and psychiatric hospitalizations (*n* = 1.6 million) in Stockholm County, Allgulander

(1996) found that 0.04% of "prescribed medication" users (including benzodiazepines) were ever admitted for medical problems relating to their drug use. In a study of 5,426 physicians randomly selected from the U.S. physicians American Medical Association database, Hughes et al. (1992) found that although 11.9% had used benzodiazepines in the past year, only 0.6% met DSM-III-R (American Psychiatric Association 1987) criteria for benzodiazepine abuse and 0.5% met criteria for benzodiazepine dependence. In 1990, the American Psychiatric Association task force concluded that benzodiazepines were not normally drugs of abuse, but noted that people who abused alcohol, cocaine, and opiates were at increased risk for benzodiazepine abuse (Salzman 1991).

Although some patients undergoing chronic therapy increase their benzodiazepine dose over time—39% in one study (Khan et al. 1981) and 50% in another (Maletzky and Klotter 1976)—the mean increase is only a small one. A number of studies have noted no increase in dosage with chronic therapy of duration from 1 to 2.5 years, even though many of the patients had residual symptoms that would have benefited from a dose increase or more intensive or additional treatment strategies (Pollack et al. 1986; D. V. Sheehan 1987). It has been reported that nonanxious subjects and those with low anxiety levels find benzodiazepines dysphoric (Reed et al. 1965), prefer placebo to diazepam (Johanson and Uhlenhuth 1978, 1980), or rate their mood as less happy and pleasant after they were given 10 mg of diazepam (Svenson et al. 1980).

Although the data suggest that the prevalence of benzodiazepine abuse or dependence is generally low, this is not true among those who abuse alcohol and other drugs. In a study of chronic alcoholic individuals who were high consumers of benzodiazepines, 17% got their benzodiazepines from nonmedical sources (Busto et al. 1983). In a study of 1,000 admissions to an alcohol treatment unit, 35% of patients used benzodiazepines, but only 10% of the total sample were considered abusers or misusers (Ashley et al. 1978). A study of 427 patients seeking treatment in Toronto who met DSM-III (American Psychiatric Association 1980) criteria for alcohol abuse or dependence found that 40% were recent users and 20% had a lifetime history of benzodiazepine abuse or dependence. Women, unemployed individuals, and those with personality disorder were at higher risk for dependence. The current benzodiazepine users were more likely to endorse psychological distress and depression and have a lifetime history of an anxiety disorder (H. E. Ross 1993). On the other hand, only 5% of 108 alcoholic patients treated for a year with benzodiazepines for anxiety and tension showed evidence of abuse, and 94% felt it helped them function and remain out of hospital (Rothstein et al. 1976). Benzodiazepine abuse liability has been shown for abstinent alcoholic men (Ciraulo et al. 1988) and in the sons and daughters of alcoholic individuals (Ciraulo et al. 1989, 1996). Enhanced sensitivity to the effects of benzodiazepines on frontal electroencephalographic activity was found to correlate with euphoric subjective responses in abstinent alcoholic individuals (Ciraulo et al. 1997).

Benzodiazepines were the primary drug of abuse in one-third of polydrug abusers (Busto et al. 1986), in 29% of 113 drug abusers admitting to the street purchase of diazepam in the previous month (Woody et al. 1975), and in 40% of patients at a methadone maintenance clinic (Woody et al. 1973). The principal reasons for benzodiazepine use among drug addicts are self-treatment of withdrawal symptoms, relief from rebound dysphoria, or potentiation of alcohol or street drug effects (Petera et al. 1987). In one study at an addictions treatment center, 100% of urine samples tested were positive for benzodiazepines and 44% were positive for multiple benzodiazepines, nonprescribed (Igochi et al. 1993). A survey of patients at three different methadone maintenance clinics found that 78%–94% admitted to a lifetime use of benzodiazepines and 44%–66% admitted to use in the prior 6 months. They also expressed a preference for diazepam, lorazepam, and alprazolam over chlordiazepoxide and oxazepam (Darke et al. 1995). Intravenous benzodiazepine use is more likely in polydrug users. In Australia, 48% of heroin users sampled injected benzodiazepines, with diazepam and temazepam being the most frequent. In the United Kingdom, the preference was for temazepam (Lader 1994; J. Ross et al. 1997). Snorting of benzodiazepines by cocaine addicts has been reported (M. F. Sheehan et al. 1991), primarily as a means of blunting the anxiogenic effect of cocaine and allowing for a more

pleasant and "less edgy" high from that drug. There is minimal evidence that sustained-release formulations may have less potential for abuse than do immediate-release formulations (Mumford et al. 1995). Flunitrazepam (Rohypnol), a benzodiazepine that is not legally available in the United States, has been popular as a party drug and is sold as "rophies," "roofies," and "roach." When mixed with alcohol, it has very strong sedating and amnestic properties and has been used as a "date rape" drug. Overall, the existing evidence suggests that the prevalence of benzodiazepine abuse is uncommon, except among those individuals who abuse alcohol and or other drugs.

Despite extensive data and discussion on this topic, the issue remains and will continue to be controversial, with strong opinions held by opposing camps. Klerman characterized these camps as "pharmacological Calvinism" and "psychotropic hedonism," respectively (Klerman 1972; Rosenbaum 2005). The pharmacological Puritans or Stoics consider anxiety to be a lesser evil than the damage that may result from psychomotor impairment (including falls in the elderly) and the risks of abuse and dependence, especially in view of the fact that alternative treatments (antidepressants and cognitive-behavior therapy) are available (Geppert 2007). The psychotropic hedonists or the Epicureans consider anxiety disorder to be more hazardous than the aforementioned risks; they believe that an anxious patient has a right to seek a life free from anxiety and fear, and they trust the patient's ability to manage this controlled substance without abuse (Geppert 2007). The middle ground suggests that we should not hesitate to prescribe benzodiazepines when it is reasonable, but that we should exercise restraint in using them when we see any evidence of abuse (Pomeranz 2007). Attempts to restrict benzodiazepine prescription have had mixed results (Schwartz 1992; Schwartz and Blank 1991). For example, the triplicate prescription program instituted in 1989 by New York State with the intent to restrict benzodiazepine prescriptions resulted in increased use of older, more dangerous sedative-hypnotics such as barbiturates and meprobamate and an increase in prescriptions for benzodiazepines in the neighboring state of New Jersey (Hemmelgarn et al. 1997; Schwartz 1992; Schwartz and Blank 1991).

MEDICOLEGAL ISSUES

In addition to issues of dependence and withdrawal described in the previous section, there are a number of potential medicolegal pitfalls in using benzodiazepines. These include issues of teratogenicity, injury, and interaction with substances.

Benzodiazepines and Pregnancy

Since anxiety disorders have their highest incidence in women during their childbearing years, the clinician may have to advise patients who are planning a pregnancy or who become pregnant while taking a benzodiazepine.

First and Second Trimesters

An important concern in the first and second trimesters is the possibility of teratogenic effects. Diazepam and desmethyldiazepam cross the placental barrier easily, and concentrations are higher in fetal blood than in maternal blood (Idanpaan-Heikkila et al. 1971). Early concern over benzodiazepine exposure in pregnancy arose because benzodiazepines act on GABA receptors and GABA is involved in palate shelf reorientation (Wee and Zimmerman 1983; Zimmerman and Wee 1984). Benzodiazepine receptors have been found in fetuses of 12–15 weeks (Aaltonen et al. 1983). The teratogenic effects of benzodiazepines, however, are a matter of controversy. Exposure to benzodiazepines has been associated with teratogenic effects, including facial clefts and skeletal anomalies in the newborn in some animal studies (R. P. Miller and Becker 1975; Walker and Patterson 1974; Wee and Zimmerman 1983; Zimmerman 1984; Zimmerman and Wee 1984) but not in others (Beall 1972; Chesley et al. 1991). Early human studies, including retrospective and case–control studies, reported an increased risk of oral clefts associated with diazepam (Aarskog 1975; Livezey et al. 1986; Safra and Oakley 1975; Saxen 1975; Saxen and Lahti 1974). These results, however, have been criticized on

methodological grounds and are contradicted by more recent prospective studies, case–control studies, and meta-analyses that show no increased risk of oral clefts related to benzodiazepine use in pregnancy (Altshuler et al. 1996; Bracken 1986; Czeizel 1988; Dolovich et al. 1998; Ornoy et al. 1998; Pastuszak et al. 1996; Rosenberg et al. 1983; Shiono and Mills 1984).

Other anomalies, including inguinal hernia, pyloric stenosis, and congenital heart defects, have been reported with first-trimester use (Bracken and Holfred 1981); hemangiomas and cardiovascular defects have been associated with second-trimester use (Bracken and Holfred 1981). Isolated cases of skeletal defects such as spina bifida, absence of left forearm, syndactyly, and absence of both thumbs have also been reported following benzodiazepine use in pregnancy (Briggs et al. 1998; Istvan 1970; New Zealand Committee on Adverse Drug Reactions 1969; Ringrose 1972), and other malformations, including dysmorphic features, growth aberrations, and abnormalities of the CNS, have been attributed to benzodiazepines (Hartz et al. 1975; Laegreid et al. 1989; Milkovich and van den Berg 1974). Pooled data from seven cohort studies, however, do not support an association between fetal exposure to benzodiazepines and major malformations (Dolovich et al. 1998).

Third Trimester and Labor

Two concerns associated with benzodiazepine use in the last trimester and through delivery are the possibilities of CNS depression and a withdrawal syndrome. Signs of CNS depression may include hypotonia, lethargy, sucking difficulties, decreased fetal movements, loss of cardiac beat-to-beat variability, respiratory depression, and thermogenesis. These symptoms in the neonate are more likely with higher doses and longer duration of benzodiazepine use by the mother. There have been numerous reports of "floppy infant syndrome" in babies born to women taking diazepam long term during pregnancy (Gillberg 1977; Haram 1977; Rowlatt 1978; Spreight 1977). Neonatal withdrawal symptoms may include hyperactivity and irritability. The occurrence of neonatal withdrawal symptoms is well documented (Barry and St. Clair 1987; Briggs et al. 1998; Cree et al. 1973; Fisher et al. 1985; Gillberg 1977; Haram 1977). Symptoms may be present at birth or appear weeks later and may continue for a period of time (Besunder and Blumer, in Schardein 1993). Elimination of benzodiazepines in the infant is slow, and it is believed that increased blood concentrations, together with an immature blood–brain barrier, contribute to newborns being more sensitive to these medications than are adults (Pastuszak et al. 1996).

Diazepam in isolated doses is safe during labor (Briggs et al. 1998). There are conflicting reports on the effect of benzodiazepines on Apgar scores. Lowered Apgar scores have been reported with benzodiazepine use in some studies (Berdowitz et al. 1981; McElhatton 1994). One study found that diazepam reduced Apgar scores only when doses greater than 30 mg were administered during labor (Cree et al. 1973). Benzodiazepines do not appear to significantly affect fetal pH (Haram 1977). Diazepam contains a buffer, sodium benzoate, that displaces bilirubin from albumin in vitro (Haram 1977). Perhaps for this reason, parenteral diazepam given during labor has been associated with a dose-dependent elevation of neonatal serum bilirubin concentration secondary to delayed bilirubin metabolism (Haram 1977).

Evaluation of the Evidence on Benzodiazepine Teratogenicity

Approximately 3% of all pregnancies end with the delivery of an abnormal live-born infant; only about 3% of these are associated with known teratogenic exposure (Coustan and Carpenter 1985). In the Collaborative Perinatal Project, the overall infant malformation rate was 6.5% (Heinonen et al. 1977).

Several sources of bias must be considered in evaluating the data on benzodiazepine teratogenicity (Dolovich et al. 1998). Retrospective studies have been criticized for "recall bias" as well as confounding and ascertainment bias. Patients using benzodiazepines tend to be a little older, and their anxiety disorder may lead to increased use of cigarettes, alcohol, caffeine, or analgesics, all of which have been associated with complications in pregnancy. Because of their well-known muscle-relaxant

and catecholamine-reducing properties, it is conceivable, but not established, that benzodiazepines might prevent spontaneous abortions of an already malformed fetus. It is also possible that the underlying anxiety disorder itself may be associated with fetal complications (Cohen et al. 1989; Crandon 1979; Istvan 1986). Large population studies are needed in order to control for these confounding factors. In the meantime, the direction of the evidence would suggest that caution and conservative advice are prudent.

Advice to Patients Planning a Pregnancy

If a patient taking a benzodiazepine plans a pregnancy, it is best to advise her to be off the medicine during her pregnancy. Benzodiazepines should always be discontinued very slowly. Some patients are unable to complete taper or tolerate the recurrence of their anxiety disorder and the consequent disability in work, social life, and family life. It is best in all cases to make an attempt to discontinue the benzodiazepine in the hope that the patient will manage without it before conceiving. Patients who are unable or unwilling to stop their benzodiazepine should be encouraged to use the lowest dose possible, preferably on an as-needed schedule. All patients are encouraged to have discontinued their benzodiazepine before the last 2 months of pregnancy. Withdrawal from benzodiazepines in a premature infant could tip the balance against healthy survival. It is common for panic disorder patients to experience a significant worsening of their panic disorder during the postpartum period. The benzodiazepine can be restarted immediately postpartum if they agree not to breast feed.

Management During an Unplanned Pregnancy

It is estimated that almost half of all pregnancies in the United States are unplanned (Skrabanek 1992). It is not unusual for a patient who has been taking a benzodiazepine for months or years to come to a regular office visit and announce that she is pregnant. She now wonders whether she should abruptly stop the benzodiazepine or have a therapeutic abortion. The first recommendation is to ensure that the patient does not abruptly stop the benzodiazepine. Abrupt withdrawal could precipitate a withdrawal seizure and even a miscarriage. Typically, by the time she realizes that she is pregnant, the period for organogenesis (8–9 weeks) is past. The first step is to spend time discussing these issues with the pregnant patient and her family and then enter a detailed record of this discussion into the medical record. Consulting with a colleague on this issue for a second opinion may be helpful. The patient can be told that there is no compelling data to support the view that discontinuing the benzodiazepine will decrease the earlier-mentioned expected 3% risk of having a fetal complication (Coustan and Carpenter 1985). However, physicians prefer their pregnant patients to not be taking any medication, as the patients in these 3% of cases might blame the complication on the benzodiazepine, even if there is no association, and sue them. The next step is to plan carefully with her a very slow withdrawal of the benzodiazepine over weeks rather than over days. A therapeutic abortion is not indicated after routine use of a benzodiazepine in the first or second trimester, as the associated abnormalities are rarely life-threatening.

Breast Feeding

Early on, neonates were found to have only limited capacity to metabolize diazepam (Morselli et al. 1973). Benzodiazepines are excreted in breast milk (Llewellyn and Stowe 1998). Because of the neonate's limited capacity to metabolize these drugs, they can potentially accumulate and cause sedation, lethargy, and loss of weight in the nursing infant. Although the extent to which benzodiazepines actually accumulate in the serum of breast-feeding infants is a matter of debate (Birnbaum et al. 1999), and three decades of studies support a low incidence of toxicity and adverse effects (Birnbaum et al. 1999; Llewellyn and Stowe 1998), caution taking benzodiazepines while breast-feeding is advised. Individualized risk–benefit assessments are recommended with the goal of minimizing, if not avoiding, infant exposure to benzodiazepines in breast milk.

Psychomotor Impairment

Another area of risk of benzodiazepine use relates to issues of psychomotor impairment resulting in injury. Examination of the medical records of a group of benzodiazepine users and nonusers who were part of a health maintenance organization found that the benzodiazepine users were more likely to experience at least one episode of accident-related health care and a greater number of accident-related inpatient days and also utilized significantly more non-accident-related health care services than did nonusers. Accident-related utilization of health care was more likely in the first month after the drug was prescribed (Oster et al. 1987). In the elderly, the issue of benzodiazepine use increasing the risk for falls and fractures is of great concern because hip fractures are associated with increased morbidity and mortality. A number of studies (Boston Collaborative Drug Surveillance Program 1973; Cummings et al. 1995; Greenblatt et al. 1977; Hemmelgarn et al. 1997; Ray et al. 1992; Roth et al. 1980) have found a greater risk for falls with the use of long-half-life benzodiazepines, and others (Cumming and Klineberg 1993; Herings et al. 1995; Leipzig et al. 1999) have found the risk to be greater with short-half-life drugs. A more recent study (Wang et al. 2001) found the risk for hip fracture in the elderly to be the same with the use of short- or long-half-life benzodiazepines. They did find that the risk increased when benzodiazepine dosages were >3 mg/day in diazepam equivalents. They also found the greatest risk to be shortly after initiation of therapy and after 1 month of continuous use. A 5-year prospective cohort study followed a large group of elderly people newly exposed to benzodiazepines (Tamblyn et al. 2005). The risk of injury varied by benzodiazepine, was independent of its half-life, and was highest for oxazepam, flurazepam, and chlordiazepoxide. The elderly using benzodiazepines are at greater risk of a motor vehicle accident (Hemmelgarn et al. 1997). On the other hand, a study of the effect of New York State requiring triplicate forms for prescribing benzodiazepines showed that despite a 50% drop in the number of prescriptions written, there was no significant change in age-adjusted risk for hip fractures (Wagner et al. 2007).

Patients receiving benzodiazepines are nearly five times more likely than nonusers to experience a serious motor vehicle accident (Skegg et al. 1979). In the first 2 weeks of benzodiazepine use, there is a severalfold excess risk for hospitalization related to accidental injury compared with persons using antidepressants or antipsychotics (Neutel 1995).

In a review of minor tranquilizers and psychomotor performance, the data overall support impairment by the few compounds studied—diazepam, lorazepam, and alprazolam. Generally, behavioral tolerance does not develop with chronic dosing (Smiley 1987). The problem with the psychomotor (driving) studies is that it is not clear how well these mirror real-life situations. In terms of utilization of medical services due to accidents, it is not yet resolved how much is due to the drug and how much is due to the illness itself, as there are no placebo-controlled studies. However, it is good practice to warn patients about the potential for sedation and psychomotor impairment with benzodiazepine use. They should be advised to be cautious when performing skilled tasks, driving, or working with machinery.

Patients should be advised to avoid the use of alcohol or sedating antihistamines when taking benzodiazepines, as there are potentially serious additive effects (Van Steveninck et al. 1996). Ethanol has effects on the GABA–benzodiazepine receptor complex. Brain benzodiazepine levels are influenced by alcohol ingestion. Alcohol decreases triazolam levels, increases diazepam levels, and does not change chlordiazepoxide levels (Castaneda et al. 1996).

The best protection is a discussion of these issues with the patient prior to prescribing a benzodiazepine. This discussion, including cautionary statements about driving or using dangerous appliances, should be documented in the chart at the start of therapy. The patient should be educated about potentiation by alcohol or other sedating drugs. He or she should be strongly advised never to abruptly discontinue the medicine because of a risk of seizures (Noyes et al. 1986), and this should be documented. Prescribing benzodiazepines for patients with a current or lifetime history of substance abuse or dependence should be done infrequently and only after documenting a risk–benefit discussion in the chart. It is good practice to routinely screen for substance abuse before prescribing

a benzodiazepine and to document that this was done. In one outpatient clinic, there was no information about alcohol use recorded in the charts of 57% of patients prescribed benzodiazepines (Graham et al. 1992).

CONCLUSION

Benzodiazepines, if given in adequate doses, are effective in the treatment of anxiety. They have a lower mortality and morbidity per million prescriptions than some of the alternatives (Girdwood 1972). They are quicker in onset of action, easier for the clinician to use, associated with better compliance, and less subjectively disruptive for the patient than any of the other medication alternatives. Until they are replaced by another class of medicine that is safer, better tolerated, and as rapidly effective, it is likely that they will continue to be prescribed to a significant proportion of patients. It is also likely that we will see a shift toward the use of sustained-release formulations of benzodiazepines, since these formulations may have less abuse liability (Mumford et al. 1995) and blunt the peaks of toxicity and the troughs of symptom recurrence that are often problematic in the chronic management of such patients.

Chapter 25. Buspirone and Gepirone

BUSPIRONE AND GEPIRONE: INTRODUCTION

Evidence of altered central serotonergic function exists for several of the psychiatric disorders, especially the mood and anxiety disorders. Discovery of the serotonin$_{1A}$ (5-HT$_{1A}$) receptor was instrumental in linking modulation of serotonin neurotransmission to anxiety symptoms. Similarly, the tricyclic antidepressants (TCAs) and the selective serotonin reuptake inhibitors (SSRIs) implicated serotonin in the pathophysiology and treatment of depression.

The notion that serotonin (5-HT) plays a role in the treatment of anxiety initially arose from the discovery that both acute and chronic administration of benzodiazepines reduced turnover of 5-HT in rat brain and that administration of para-chlorophenylalanine (pCPA), an inhibitor of serotonin synthesis, mimics the effects of benzodiazepines in behavioral models of anxiety utilizing a conflict paradigm (Wise et al. 1972). Subsequent characterization of subtypes of 5-HT receptor, especially the 5-HT$_{1A}$ and 5-HT$_2$ receptors, and discovery of the 5-HT$_{1A}$ receptor partial agonist buspirone inferred that serotonin plays a key role in anxiolysis (Eison and Eison 1994). Because both the benzodiazepines and buspirone were found to pharmacologically reduce 5-HT impulse flow, albeit by different mechanisms, it was hypothesized that enhanced serotonergic tone might be an underlying factor in the etiology of anxiety disorders.

THE 5-HT$_{1A}$ RECEPTOR

The development of specific pharmacological ligands in combination with molecular cloning and subsequent expression in heterologous systems has led to the unequivocal identification of 14 different 5-HT receptor subtypes (Hoyer et al. 2002). Except for the 5-HT$_3$ receptor, all 5-HT receptor subtypes are members of the large family of seven transmembrane domain G protein–coupled receptors (Pierce et al. 2002). The 5-HT$_{1A}$ receptor is one of the most important receptors in this class and of the subfamily that couples negatively to adenylyl cyclase (De Vivo and Maayani 1986). It has been the most extensively studied 5-HT receptor because 1) identification of the selective agonists, including 8-OH-DPAT (Hamon et al. 1984) and the azapirones, and specific receptor antagonists (WAY-100635; Fletcher et al. 1996) have allowed for strict pharmacological classification; 2) it is the first 5-HT receptor to be cloned and sequenced (Fargin et al. 1988; Kobilka et al. 1987); 3) polyclonal antibodies have been generated for subcellular distribution studies in brain (Azmetia et al. 1996; El Mestikawy et al. 1990); and 4) human, rat, and mouse receptors have been cloned and sequenced (Albert et al. 1998; Charest et al. 1993; Fargin et al. 1988) in support of the translational studies. Furthermore, several studies have determined that the 5-HT$_{1A}$ receptor may play a role in neural development (del Olmo et al. 1998; Gross et al. 2002). Taken together with the recent implications of a salutary effect of chronic SSRI treatment on neurogenesis (Duman et al. 2001) and the fact that 5-HT$_{1A}$ agonists exhibit positive treatment effects in both anxiety and depressive states (Robinson et al. 1989a), the body of evidence suggests that this receptor plays a central role in neuropsychiatric disorders.

Distribution and Function

The regional distribution of the 5-HT$_{1A}$ receptors was established using both selective agonist and

antagonist ligands with antibodies that were raised against unique peptide sequences within the receptor protein as well as mRNA densities. Studies utilizing the full agonist [^{3}H]8-OH-DPAT (8-hydroxy-2-[*N*-dipropylamino]-tetralin) and the putative 5-HT$_{1A}$ receptor antagonist ligand [^{3}H]WAY-100635 reveal high levels of specific binding in hippocampus, raphe nuclei, amygdala, hypothalamus, and cortex (Burnet et al. 1997; Palacios et al. 1990). The results with autoradiography were mirrored by the finding of localization of messenger RNA (mRNA) densities in these regions as well (Burnet et al. 1995; Chalmers and Watson 1991). At the subcellular level, the receptor was found to be localized on cell bodies and dendrites of 5-HT–containing neurons projecting to limbic brain regions. In limbic regions receiving input from 5-HT–containing neurons, particularly hippocampus and cortex, 5-HT$_{1A}$ receptors are located predominantly postsynaptically (Palacios et al. 1990; Riad et al. 2000).

Pharmacological and Clinical Implications

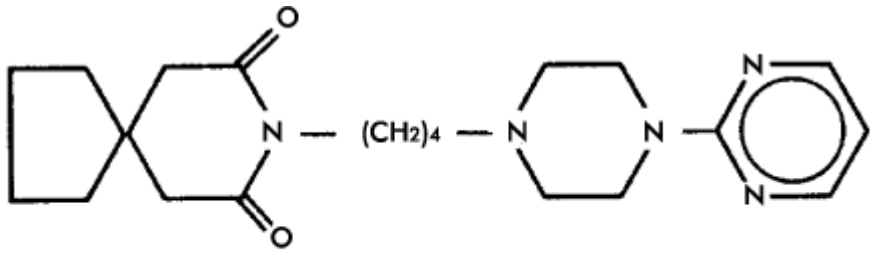
The high regional density of 5-HT$_{1A}$ receptors in midbrain, hippocampus, and limbic areas of the brain is consistent with the notion that 5-HT neurotransmission modulates mood and anxiety. These brain regions of high density of 5-HT$_{1A}$ receptors play key roles in regulating diverse vital processes, including thermoregulation, endocrine function, appetite, aggressive and sexual behavior, and mood. Mice lacking the 5-HT$_{1A}$ receptor gene exhibit various manifestations of anxious behavior with stress (Parks et al. 1998) and exhibit increased autonomic hyperactivity when exposed to foot shock (Pattij et al. 2002).

5-HT$_{1A}$ receptors located on 5-HT–containing neurons in midbrain raphe regions modulate release of 5-HT at synapses in forebrain. These somatodendritic autoreceptors control impulse flow (Yocca 1990), synthesis (Yocca 1990), and release (Sharp et al. 1989) of neurotransmitter from ascending 5-HT–containing neurons. Postmortem study of suicide victims reveals enhanced radioligand binding of [^{3}H]8-OH-DPAT to the inhibitory 5-HT$_{1A}$ autoreceptors located in the dorsal raphe, providing pharmacological evidence in support of the hypothesis that depressed suicide victims may have diminished activity of 5-HT neurons (Stockmeier et al. 1998). Blunted 5-HT$_{1A}$ receptor–mediated response of corticosteroids has been reported in patients with major depressive disorder (MDD), suggesting that there is desensitization of these receptors in patients with anxiety and depression (Lesch 1992; Rausch et al. 1990; Stahl 1992). In regions postsynaptic to ascending raphe neurons such as prefrontal cortex, altered levels of 5-HT$_{1A}$ receptor binding have been found in the prefrontal cortex of depressed suicide victims (Matsubara et al. 1991), although conflicting evidence exists (Arranz et al. 1994; Cheetham et al. 1990).

The 5-HT$_{1A}$ Receptor and Partial Agonists

Given the large body of work implicating 5-HT in the etiology and treatment of affective disorders, and the role of the 5-HT$_{1A}$ receptor in the control of central 5-HT neurotransmission, it is not surprising to find that drugs targeting this receptor would have an impact in the treatment of mood disorders. It would seem logical to implicate this receptor because 5-HT–acting drugs, such as TCAs and monoamine oxidase inhibitors (MAOIs), increase synaptic concentrations of the neurotransmitter. Furthermore, there is a region-dependent difference in responses to 5-HT$_{1A}$ agonists at pre- and postsynaptic 5-HT$_{1A}$ receptors. This may be attributable to a difference in regional receptor reserve (Meller et al. 1990; Yocca et al. 1992). Therefore, the proper degree of agonism at both pre- and postsynaptic 5-HT$_{1A}$ receptors may be critical to achieving an optimal level of efficacy/tolerability using this pharmacological approach.

Drugs acting as partial agonists represent an attractive strategy for discovery of new psychiatric agents, potentially offering therapeutic advantages (Yocca and Altar 2006). It is postulated that this emerging class of successful central nervous system drugs acts in part by signal attenuation at one or multiple target receptors. Partial agonist compounds, such as buspirone and aripiprazole, produce a



desired therapeutic response, with excellent safety and tolerability. Interestingly, among the first drugs in this category were selective partial agonists of 5-HT_{1A} receptors. These agents have undergone extensive clinical development for treatment of both generalized anxiety disorder (GAD) and MDD. As yet, only buspirone has received marketing approval. Gepirone, a 5-HT_{1A} agonist with greater intrinsic activity postsynaptically, has been extensively investigated as an anxiolytic and as an antidepressant agent. A new drug application (NDA) for gepirone extended-release (ER) for treatment of MDD recently failed to obtain U.S. Food and Drug Administration (FDA) approval. An NDA for GAD and hyposexual desire disorder by the drug sponsor is under consideration. Several other selective 5-HT_{1A} agonists (ipsapirone, flesinoxan, tandospirone) have been unsuccessful in clinical development for a target clinical indication of either GAD or MDD.

BUSPIRONE

History and Development

Buspirone hydrochloride, an azaspirodecanedione derivative (Figure 25–1), was synthesized in 1968 in the laboratories of Mead Johnson by Wu et al. (1969). Based on positive findings in conditioned-avoidance testing in rats, buspirone was originally studied clinically as a putative antipsychotic agent. It was projected to be largely devoid of the typical side effects of the antipsychotic class of drugs, but clinical trials failed to demonstrate usefulness in the treatment of schizophrenia (Sathananthan et al. 1975). Further study revealed that a single dose of buspirone had a marked taming effect in aggressive monkeys (Tompkins et al. 1980). In various behavioral models of anxiety in rodents, buspirone inhibited foot shock–induced fighting and prevented shock-induced suppression of drinking behavior, both screening tests predictive of anxiolytic effects (Riblet et al. 1982). At that time, minimal data were available on the molecular pharmacology of buspirone. However, Riblet et al. (1982) reported that buspirone displaced [^{3}H]spiperone from dopamine D_2 receptors in rat striatal membranes with an IC_{50} of 260 nM and demonstrated a right shift in binding activity in the presence of guanosine triphosphate (GTP), suggesting that it was a D_2 agonist. Until the subsequent finding of high affinity binding to the newly discovered 5-HT_{1A} receptor some 4 years later, the basis for the anxiolytic activity of buspirone was thought to be dopaminergic in origin.

A Phase II proof-of-concept study in patients with DSM-II (American Psychiatric Association 1968) anxiety disorder demonstrated significant anxiolytic treatment effects of buspirone compared with placebo (Goldberg and Finnerty 1979), leading to a full-scale clinical development as an antianxiety agent (Robinson 1991).

Pharmacological Profile

Buspirone is relatively inactive in receptor binding studies in vitro at noradrenergic, cholinergic, and histaminergic sites. It does not displace [^{3}H]diazepam or [^{3}H]nitrazepam from the benzodiazepine receptor complex or affect γ-aminobutyric acid (GABA) modulation of the benzodiazepine binding site

(Riblet et al. 1982). Although buspirone does displace [^{3}H]spiperone from rat striatal membranes at relatively high concentrations (Mennini et al. 1986, 1987), dopamine receptor binding is believed to play no role in either the therapeutic or side effects of buspirone (Eison et al. 1991).

The discovery that nanomolar quantities of buspirone displaced [^{3}H]5-HT from hippocampal membranes (Glaser and Traber 1983) led to elucidation of interactions of buspirone with specific central 5-HT receptors. Buspirone was found to inhibit [^{3}H]5-HT binding to cortical and hippocampal membranes (Skolnick et al. 1985). Later, it was determined that buspirone selectively displaced [^{3}H]8-OH-DPAT from 5-HT$_{1A}$ receptor binding sites in rat hippocampal membranes with high affinity (24 nM) (Yocca 1990).

The antianxiety properties of buspirone appear to be exerted through its actions at both pre- and postsynaptic 5-HT$_{1A}$ receptors (Eison and Eison 1994; Yocca 1990). At presynaptic 5-HT$_{1A}$ receptors located in the dorsal raphe, buspirone acts as a full agonist, inhibiting neuronal 5-HT synthesis and firing, whereas at postsynaptic receptors in hippocampus and cortex, it functions as a partial agonist. It is postulated that the anxiolytic effect of buspirone is dependent on its serotonergic actions in the presence of a preexisting deficiency of this neurotransmitter.

Buspirone does differ from benzodiazepines because of its lack of inhibition of spontaneous motor activity, effects on motor coordination, and induction of the serotonin syndrome in rats (Eison et al. 1991). Buspirone lacks abuse potential and does not impair psychomotor performance either alone or in combination with ethanol, unlike the benzodiazepines (Smiley 1987; Sussman and Chow 1988). The behavioral effects of buspirone and benzodiazepines differ in a number of animal models of anxiety (Barrett and Witkin 1991). Unlike benzodiazepines, buspirone does not uniformly increase punished or conflict responding in rats and monkeys, and when increased responding is observed, the magnitude of response tends to be less than that of a benzodiazepine.

By contrast, in pigeons buspirone enhances punished response with a magnitude equivalent to benzodiazepines. This finding is characteristic of the 5-HT$_{1A}$ receptor agonists, including 8-OH-DPAT, gepirone, and agents of this class. Other classes of psychotropic drugs—for example, TCAs, SSRIs, opioids, antipsychotics, and psychomotor stimulants—do not increase responding in this behavioral model. Buspirone also enhances exploratory and social interaction behaviors in rodents, similar to the benzodiazepines.

Of interest, 5-HT$_{1A}$ agonists also demonstrate activity in an animal model of depression. Similar to imipramine, desipramine, and fluoxetine, 5-HT$_{1A}$ agonists such as 8-OH-DPAT and the azapirones buspirone, gepirone, ipsapirone, and tandospirone produce antidepressant-like behavior in the forced-swim test in rats (Wieland and Lucki 1990). This occurs in the absence of changes in locomotor activity and is not diminished by pretreatment with the 5-HT synthesis inhibitor pCPA, suggesting that 5-HT$_{1A}$ agonists produce an antidepressant response through postsynaptic effects on 5-HT$_{1A}$ receptors. The major azapirone metabolite, 1-(2-pyrimidinyl) piperazine (1-PP), is devoid of behavioral activity in this test. The finding of activity in a preclinical model of depression comports with clinical studies of both buspirone and gepirone, which are indicative of antidepressant effects.

Pharmacokinetics and Disposition

With oral administration, buspirone is subject to extensive first-pass metabolism, with an elimination half-life of 3 to 4 hours (mean) in normal subjects (Gammans and Johnston 1991). In the liver, buspirone undergoes extensive metabolic transformation by cytochrome P450 3A4 enzymes. Ingestion of food prolongs the elimination half-life of buspirone, as is also the case with significant hepatic and renal impairment. The pharmacokinetics of buspirone in elderly patients do not differ importantly from those in young adults (Gammans et al. 1989).

It was known that buspirone had three major metabolites of varying pharmacological activities:

5-hydroxybuspirone (5-OH-Bu), 8-hydroxybuspirone (8-OH-Bu), and 1-PP. Because buspirone blocks α_2-adrenergic receptors, it is postulated that unwanted noradrenergic effects of 1-PP might be deleterious in patients experiencing benzodiazepine withdrawal or panic attacks. The potential therapeutic advantage, if any, of 5-HT_{1A} partial agonists lacking the 1-PP metabolite is presently unknown.

Identification of 6-Hydroxybuspirone as a Major Active Metabolite

More recently, conversion of buspirone to the metabolite 6-hydroxybuspirone (6-OH-Bu) by means of biotransformation in human liver microsomes was identified as the predominant metabolic pathway involved in the hepatic clearance of buspirone (Zhu et al. 2005). Plasma levels of 6-OH-Bu were found to be 40-fold greater than those of buspirone following oral administration in humans (Dockens et al. 2006). In vitro, 6-OH-Bu demonstrates high affinity (25 nM) and partial agonist activity for the 5-HT_{1A} receptor, whereas 6-OH-Bu in vivo exhibits anxiolytic activity in the fear-induced ultrasonic vocalization paradigm (F. D. Yocca, unpublished observations, June 1998). The plasma clearance, volume of distribution, and elimination half-life of 6-OH-Bu are similar to those of buspirone, but the bioavailability of 6-OH-Bu is significantly greater (19% vs. 1.4%; Wong et al. 2007). As with buspirone, 6-OH-Bu demonstrates in vivo occupancy of 5-HT_{1A} receptors after intravenous administration in rats, with a fourfold greater potency exhibited in dorsal raphe than in the hippocampus (Wong et al. 2007). Taken together, these findings suggest that 6-OH-Bu contributes significantly to the therapeutic effect of buspirone.

Switching From Benzodiazepine Therapy to Buspirone

A major pharmacodynamic interaction occurs in patients previously treated with benzodiazepines on switching to buspirone. Both tolerability and the therapeutic response to buspirone differ significantly in anxious patients naive to benzodiazepine treatment compared with patients previously treated with a benzodiazepine (DeMartinis et al. 2000; Schweizer and Rickels 1986). Meta-analysis of placebo-controlled efficacy trials of buspirone revealed that GAD patients with either no prior benzodiazepine treatment or temporally remote benzodiazepine treatment (>6 months previously) improved more with buspirone therapy than patients recently treated with a benzodiazepine. The mechanism of this pharmacodynamic interaction is not established, but it may reflect a subtle underlying benzodiazepine withdrawal syndrome (possibly exacerbated by 1-PP). It is also possible that previously treated patients might be preconditioned by benzodiazepine therapy and hold expectations involving the mildly euphoriant, sedating properties of a benzodiazepine. One wonders if successful past treatment with a benzodiazepine influences future attempts to treat anxiety with a nonbenzodiazepine such as buspirone. In the placebo-controlled trials, patients who had received recent prior benzodiazepine therapy and were randomly assigned to the benzodiazepine treatment group may have benefited from reinstitution of benzodiazepine treatment, with resultant amelioration of an unrecognized (subclinical) withdrawal syndrome.

Mechanism of Action

While it has been clearly established that the anxiolytic effects of buspirone are mediated by its actions on 5-HT receptors in the limbic system (Eison and Eison 1994; Yocca 1990), buspirone also has unrelated neuroendocrine effects reflective of a complex pharmacology. Preclinical studies have shown buspirone possesses characteristics of both a D_2 agonist and antagonist in addition to being a 5-HT_{1A} agonist. These pharmacological attributes are important in understanding the neuroendocrine actions of buspirone, because it is well established that prolactin is regulated by the neurotransmitter dopamine acting via D_2 receptors in the anterior pituitary gland. Furthermore, the evidence indicates that 5-HT_{1A} receptors regulate neuroendocrine hormones, such as growth hormone, adrenocorticotropic hormone (ACTH) release, and corticosterone (Gilbert et al. 1988; Pan and Gilbert 1992; Van de Kar et al. 1985). This notion was further substantiated in a study by Vicentic et al.

(1998) in which increases in plasma levels of oxytocin, ACTH, and corticosterone induced by the selective 5-HT_{1A} agonist 8-OH-DPAT were blocked by administration of the selective 5-HT_{1A} antagonist WAY-100635.

Meltzer and Fleming (1982) showed that buspirone produces a dose-dependent increase in rat plasma prolactin levels. Furthermore, buspirone has been shown to antagonize the inhibitory effects of dopamine on prolactin release from the rat pituitary gland in vitro, illustrative of its partial agonist activity at D_2 receptors (Meltzer et al. 1991). Buspirone enhances secretion of corticosterone in rats, whereas in patients it increases prolactin, growth hormone, and corticosterone levels when administered orally (Meltzer et al. 1991). In healthy volunteers, buspirone, ipsapirone, and gepirone have been shown to increase plasma cortisol, prolactin, and growth hormone and to decrease body temperature (Cowen et al. 1990). Buspirone stimulation of prolactin and corticosterone secretion in the rat is enhanced by pretreatment with pCPA, whereas spiperone inhibits buspirone-induced increases in rat corticosterone secretion (Meltzer et al. 1991). Pindolol, a 5-HT_{1A} antagonist, does not block the buspirone-induced increase in prolactin (Meltzer et al. 1991). Taken together, these results suggest that the neuroendocrine effects of buspirone in rat and man are complex, exhibiting pharmacological properties of both a dopamine antagonist and a 5-HT_{1A} agonist.

Indications and Efficacy

Generalized Anxiety Disorder

The efficacy of buspirone was established in a series of well-controlled trials conducted in the 1970s and 1980s in a patient population with the DSM-II diagnosis of anxiety disorder (Robinson 1991). The clinical development program of buspirone as an anxiolytic agent was undertaken after positive findings in a placebo-controlled proof-of-concept study in anxious patients (Goldberg and Finnerty 1979). It is of interest that the study investigators commented on the possibility that buspirone possesses antidepressant as well as anxiolytic properties. In a series of Phase III placebo-controlled clinical trials comparing buspirone and diazepam, the efficacy of these two anxiolytics was comparable in patients fulfilling diagnostic criteria for DSM-II anxiety neurosis (Boehm et al. 1990a; Goldberg and Finnerty 1982; Rickels et al. 1982). In these double-blind dosage titration studies, buspirone and diazepam were prescribed on a thrice-daily schedule in dosages (mean) ranging from 20 to 25 mg/day during 4 weeks of treatment.

By the time the FDA granted marketing approval of buspirone in 1986, the newest DSM classification system, DSM-III (American Psychiatric Association 1980), had replaced anxiety neurosis with the diagnostic category of GAD. As a result of this change, retrospective statistical analyses of the placebo-controlled efficacy trials were carried out. Analyses of Hamilton Anxiety Scale (Ham-A; Hamilton 1959) and other symptom ratings were found to be consistent with a diagnosis of DSM-III GAD, so buspirone received FDA-approved labeling for this clinical indication.

In the controlled trials, buspirone was noted to have a slightly slower onset of therapeutic effect than the benzodiazepines (Enkelmann 1991; Pecknold et al. 1989; Rickels 1990). This perceived slower onset of effect was attributable to differences between buspirone and benzodiazepines in early relief of somatic anxiety symptoms but was not due to a difference in relief of psychic anxiety symptoms. It was postulated that absence of sedation with buspirone contributed to a perception of more gradual onset of anxiolytic effect, because relief of somatic anxiety, particularly insomnia, was only manifest with buspirone treatment after psychic anxiety symptoms had abated, whereas the immediate sedating properties of benzodiazepines accounted for a perception of faster onset of therapeutic benefit. A similar slower onset of effectiveness in anxiety disorders occurs with imipramine (Rickels et al. 1993) and SSRI treatment (Rickels et al. 2003).

A longer-term 6-month double-blind comparative trial of buspirone and benzodiazepines found a

similar slow onset of anxiolytic effect with buspirone compared with clorazepate during the first 4 weeks of treatment (Rickels et al. 1988). However, with ongoing treatment the therapeutic response to the two drugs was thereafter similar. On double-blind termination of treatment after 6 months, patients who stopped clorazepate abruptly relapsed during a 4-week observation period, whereas the buspirone group experienced no symptom changes. These findings confirmed the observation of others (Fontaine et al. 1984; Noyes et al. 1988) that rapid return of symptoms on discontinuation of clorazepate is attributable to a benzodiazepine withdrawal syndrome and not to recrudescence of symptoms of the underlying anxiety disorder, because this did not occur with abrupt discontinuation of buspirone.

Possible clinical benefit of buspirone therapy on the benzodiazepine withdrawal syndrome was assessed in 15 chronic anxiety patients representing 146 cumulative years of tranquilizer exposure who had previously failed in attempts at both abrupt and gradual withdrawal of benzodiazepine treatment (Schweizer and Rickels 1986). In this study, addition of buspirone overlapping with tapering of benzodiazepine dosage failed to ameliorate benzodiazepine withdrawal symptoms, and none of the patients could be maintained on buspirone alone after complete withdrawal of benzodiazepine treatment. In several other studies, buspirone appears to have only modest beneficial effect on the benzodiazepine withdrawal syndrome (DeMartinis et al. 2000; Shiaie et al. 1995; Udelman and Udelman 1990).

Since the approval and availability of buspirone for clinical use, a limited number of well-controlled efficacy trials in GAD were conducted. One reason for this was its relatively short product life cycle and the fact that the drug sponsor was developing a successor to buspirone, the azapirone analog gepirone. After buspirone's approval, several placebo-controlled efficacy studies in anxiety disorders were conducted, and they reported that it had significant anxiolytic properties (Enkelmann 1991; Laakman et al. 1998; Lader and Scotto 1998; Murphy et al. 1989; Pecknold et al. 1989; Scheibe 1996). In a family practice setting, Boehm et al. (1990a) studied 60 patients with anxiety disorder in a placebo-controlled trial comparing the benzodiazepine clobazam and buspirone. In this 3-week treatment trial, treatment with clobazam and buspirone was equally effective and superior to placebo in relieving anxiety, as measured by the Ham-A and the Clinical Global Impressions–Improvement (CGI-I) scale.

In a large placebo-controlled, fixed-dose multicenter study comparing buspirone and venlafaxine extended-release (XR) in GAD, neither venlafaxine XR nor buspirone differed significantly from placebo on the primary efficacy outcome measure, Ham-A total score (Davidson et al. 1999). On several secondary outcome measures, buspirone treatment appeared less effective than venlafaxine XR but did result in significant improvement in CGI-I scores compared with placebo treatment. One limitation of this trial was utilization of a fixed-dose study design, which underestimates treatment effects as compared with a flexible-dose study design in depression efficacy trials (Robinson and Khan 2004).

Acute treatment of chronically anxious patients is often best managed initially with a benzodiazepine; however, longer-term use of a benzodiazepine can lead to physical dependence and symptom chronicity. For this reason, some patient populations are inappropriate for benzodiazepine therapy due to history of substance abuse or potential risk of cognitive impairment. When initiating therapy with buspirone, one should inform the patient that it is less sedating, with a more gradual onset of action, than benzodiazepine treatment. Patients can be reassured that if they require long-term drug therapy, buspirone will not lead to physical dependence or withdrawal symptoms on discontinuation. Patients also should be informed that acute or long-term treatment with buspirone does not impair cognition or ability to acquire new coping skills (Rickels and Schweizer 1990).

Long-term follow-up at 40 months of patients who previously completed a prior 6-month controlled trial comparing buspirone and clorazepate revealed that none of the buspirone-treated patients was

taking either a regular or as-needed anxiolytic medication, whereas 30% of patients originally treated with clorazepate still required daily benzodiazepine therapy, and an additional 24% took benzodiazepines intermittently. Thus, more than 50% of patients treated for 6 months with clorazepate, but none of the buspirone-treated patients, were taking ongoing anxiolytic medication after 3 years (Rickels and Schweizer 1990). Scheibe (1996) reported similar observations in long-term follow-up of an acute efficacy controlled trial of patients with anxiety disorders. In this latter study, at 40 months 38% of buspirone-treated patients still required buspirone therapy, whereas 64% of patients treated with lorazepam required benzodiazepine medication.

The therapeutic advantages of buspirone treatment in elderly anxious patients include the fact the drug both is nonsedating and spares cognitive and memory functions. Buspirone has been studied in elderly patients with anxiety symptoms in a double-blind, placebo-controlled trial and shown to be safe and effective (Boehm et al. 1990b). Meta-analyses of several multicenter trials of buspirone in elderly patients also indicated that the drug is very safe and well tolerated by older patients (Ritchie and Cox 1993; Robinson et al. 1988).

Panic Disorder

Buspirone treatment has been evaluated in patients with panic disorder in placebo-controlled trials (Pohl et al. 1989; Sheehan et al. 1990). These trials did not find that buspirone diminished the number of panic attacks significantly. However, meta-analysis of the double-blind, three-arm multicenter trials comparing buspirone, imipramine, and placebo treatment found that both imipramine and buspirone had significant anxiolytic effects in panic disorder (Robinson et al. 1989b). Absence of buspirone effect on number of panic attacks is not surprising, given the findings of preclinical testing showing that buspirone causes increased firing rates of the locus coeruleus (Eison and Temple 1986) and noradrenergic hyperactivity (Charney and Heninger 1985), both manifestations of panic disorder.

Mixed Anxiety–Depression and Major Depressive Disorder

It was observed in early trials of patients with anxiety disorder and subsyndromal depression that depressive symptoms also improved significantly during buspirone treatment (Feighner et al. 1982; Goldberg and Finnerty 1979). This generated interest in the potential antidepressant properties of buspirone because of the high comorbidity of GAD and MDD (T.A. Brown and Barlow 1992). It has been suggested that GAD and MDD may exhibit differing clinical manifestations of a single underlying diathesis. Genetic studies in patients with MDD and GAD suggest that the genetic vulnerability for both disorders is largely shared (Kendler et al. 1992). Wray et al. (2007) recently described a likely genetic association between variants of the gene *PlexinA2* and anxiety disorders, providing potential evidence for the adult neurogenesis theory of depression.

Several placebo-controlled trials of buspirone have been conducted in patients with MDD and significant associated anxiety symptoms (Rickels et al. 1991; Robinson et al. 1990). For inclusion, patients with MDD were eligible if their Hamilton Rating Scale for Depression (Ham-D; Hamilton 1960) and Ham-A scores were 18 or greater and 15 or greater, respectively. Following a starting dosage of 5 mg thrice daily for 3 days, the daily dosage in these dosage titration studies ranged up to a maximum of buspirone 90 mg/day (mean, ~50 mg/day). Buspirone treatment was found to be superior to placebo treatment, with a global response rate based on CGI-I score of 70% for buspirone and 35% for placebo (Rickels et al. 1991). In a subsequent placebo-controlled study involving 177 geriatric depressed outpatients, Schweizer et al. (1998) compared buspirone and imipramine treatment for 8 weeks. There was a statistically significant treatment effect for both buspirone (mean daily dose, ~50 mg) and imipramine (mean daily dose, ~90 mg) compared with placebo treatment. Global improvement (CGI-I) with buspirone and imipramine was 80% and 86%, respectively, compared with 49% with placebo treatment.

Open-label augmentation of SSRI treatment of partially responding depressed patients leads to

further improvement (Dimitriou and Dimitriou 1998; Gonul et al. 1999; Jacobsen 1991; Landren et al. 1998). These findings were recently confirmed in a report of the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) program. Patients who initially failed an adequate therapeutic trial with an SSRI responded when their medication was augmented with either buspirone or bupropion (Trivedi et al. 2006).

We speculate that had the sponsor pursued an antidepressant clinical indication rather than a GAD indication, buspirone might well have become the first 5-HT_{1A} partial antagonist to be developed as an antidepressant drug. Presently, buspirone lives in the shadows of the antidepressant drugs with high clinical exposure and promotion. The fact that the product life cycle of buspirone was relatively short (as mentioned earlier) while all of the SSRIs pursued a clinical indication for GAD served to limit clinical investigation of buspirone's full therapeutic profile.

Nonapproved Clinical Indications

Potential clinical indications for buspirone treatment unapproved by the FDA were recently reviewed by Rickels et al. (2003). Only a few of these buspirone studies and potential clinical indications are mentioned here. Two small double-blind clinical trials indicated modest efficacy of buspirone over placebo in the symptomatic treatment of postmenopausal syndrome (C. S. Brown et al. 1990; Rickels et al. 1989). Several placebo-controlled trials showed that smoking cessation is facilitated by buspirone therapy (Hilleman et al. 1992; West et al. 1991); its main effect, however, is in smokers who are also highly anxious (Cinciripini et al. 1995). Buspirone has been assessed in a few double-blind, placebo-controlled trials involving anxious outpatients with coexisting alcohol use disorders and found to be efficacious (Rickels et al. 2003). Because buspirone lacks abuse potential and has negligible additive effects on psychomotor and cognitive functions when coadministered with alcohol (Mattila et al. 1982), it has therapeutic benefit in the management of alcohol abuse and dependence. In a recent placebo-controlled trial, buspirone was found to be efficacious in ameliorating symptoms of opioid withdrawal (Buydens-Branchey et al. 2005).

Recently, Lee et al. (2005) reported a placebo-controlled study showing beneficial effects of buspirone in migraine patients with anxiety symptoms. Buspirone has also been evaluated under double-blind conditions in patients with aggressive behavior and agitation. In a study of 26 patients Cantillon et al. (1996) demonstrated significantly greater decrease in tension with buspirone compared with haloperidol in patients with Alzheimer's disease.

Dosage and Administration

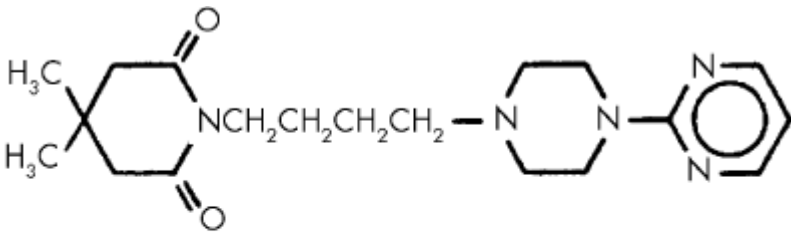
The recommended dosage of buspirone for the treatment of GAD is 15–20 mg/day initially, prescribed in divided doses, with dosage increases to 30 mg/day if indicated. The maximal daily dosage recommended is 45 mg in the United Kingdom and 60 mg in the United States. It should be mentioned, however, that in the double-blind MDD trials (described earlier), the maximal dosage allowed was 90 mg/day. Thus, higher dosages of buspirone than those prescribed for anxiety disorders may be required in the treatment of MDD, either as monotherapy or as augmentation of an SSRI.

Side Effects and Toxicology

Newton et al. (1986), summarizing data from 17 clinical trials, reported the incidence of frequently reported adverse events during buspirone treatment: dizziness (12%), drowsiness (10%), nausea (8%), headache (6%), nervousness (5%), fatigue (4%), insomnia (3%), light-headedness (3%), dry mouth (3%), and excitement (2%). No deaths by overdose of buspirone occurred during preapproval clinical development. Interestingly, patients given buspirone had similar incidences of drowsiness, insomnia, fatigue, and dry mouth as with placebo treatment, and no treatment-emergent sexual dysfunction was observed.

Extensive preclinical and clinical testing indicates that buspirone lacks abuse potential, unlike alcohol and benzodiazepines (Balster 1991). A large number of psychomotor function studies, including evaluation of complex motor driving skills and memory tasks, have documented absence of impairment with buspirone administration, unlike alcohol and the benzodiazepines (Boulenger et al. 1989; Greenblatt et al. 1994; Lucki et al. 1987; Smiley and Moskowitz 1986). Since buspirone's general availability in clinical practice, no deaths attributable to buspirone overdose alone have occurred to our knowledge. Buspirone remains an unusually safe and well-tolerated medication with no abuse liability and few drug–drug interactions except for those associated with concurrent use with MAOIs.

Drug–Drug Interactions



Buspirone does not inhibit P450 enzymes, although it causes modest elevations of haloperidol and cyclosporin A levels. Buspirone has relatively few pharmacodynamic interactions with other psychotropic drugs. Because coadministration of buspirone with MAOIs carries the potential risk of serotonin syndrome, it is contraindicated in the buspirone labeling; however, cautious use of this combination has been regarded as being safe if clinically indicated (Ciraulo and Shader 1990).

GEPIRONE

History and Development

Gepirone, an azapirone analog of buspirone, is a substituted imide synthesized in 1986 by Bristol-Myers Squibb (refer to Figure 25–2 for chemical structure). The structural alteration (gem-dimethyl substitution) between buspirone and gepirone produces a major pharmacological difference—that is, negligible D_2 receptor affinity. Gepirone exhibits a 30- to 50-fold reduction in affinity for D_2 receptors (New 1990). The fact that gepirone has high affinity and greater intrinsic activity for postsynaptic 5-HT_{1A} receptors yet lacks appreciable affinity for D_2 receptors and has activity in a variety of preclinical anxiolytic and antidepressant models supports the notion that the antidepressant properties of azapirones reside in the agonist interaction at 5-HT_{1A} receptors. Like buspirone, gepirone is chemically unrelated to the benzodiazepines and lacks sedative-hypnotic, anticonvulsant, and muscle-relaxant properties.

Given its preclinical pharmacological profile of selective action on serotonergic neurotransmission and its more complete agonist profile at postsynaptic 5-HT_{1A} receptors, gepirone was initially developed as a dual antianxiety and antidepressant agent utilizing an immediate-release formulation. Because of its short elimination half-life and suboptimal tolerability, an extended-release formulation was deemed desirable, and clinical development was switched to gepirone ER. In 1993, gepirone was outlicensed to Fabre-Kramer, and in partnership with Organon, the clinical development of gepirone ER for MDD continued. The decision by Bristol-Myers Squibb to outlicense gepirone was based on competing

depression programs within the company at that time. Organon submitted an NDA for treatment of MDD in October 1999. In its review of the application, the FDA cited insufficient evidence of efficacy due to lack of the requisite two positive well-controlled (pivotal) efficacy trials. Fabre-Kramer reassumed responsibility for gepirone and undertook additional clinical development for treatment of depression. An NDA submitted in 2007 did not receive FDA approval. Further studies with gepirone ER in depression are planned, and clinical indications for GAD and hyposexual desire disorder are being considered by the drug sponsor.

Mechanism of Action

A number of important in vitro and in vivo pharmacological studies have been undertaken with gepirone. At both pre- and postsynaptic 5-HT_{1A} receptors in native tissue, gepirone displaces [^{3}H]8-OH-DPAT from bovine dorsal raphe rat hippocampal membranes with similar affinity, which is approximately fourfold less potent than buspirone (Yocca 1990). Presynaptically, gepirone exhibits potent agonist properties. This is evident in studies measuring markers of presynaptic 5-HT_{1A} receptor stimulation (reduced accumulation of 5-HT [Yocca 1990]), reduction in hippocampal 5-HT levels measured through microdialysis (Sharp et al. 1989), and reduction in firing of 5-HT–containing dorsal raphe neurons (Blier and de Montigny 1987). At postsynaptic 5-HT_{1A} receptors, gepirone displays partial agonist properties, albeit with less potency but greater intrinsic activity than buspirone (Yocca 1990). The partial agonist nature of gepirone was demonstrated in an elegant study by Andrade and Nicoll (1987). Microiontophoretic administration of gepirone, similar to 5-HT, hyperpolarizes rat hippocampal pyramidal neurons through an interaction with 5-HT_{1A} receptors, only to a lesser degree. When gepirone and 5-HT are microiontophoretically applied simultaneously, gepirone antagonizes the full agonist effect of 5-HT. This study demonstrates the pharmacological versatility of a compound with partial agonist properties, which can function as either a receptor agonist or antagonist depending on ambient conditions. Gepirone lacks appreciable affinity for other monoamine or benzodiazepine receptors and does not bind to neurotransmitter transporter sites.

Chronic treatment with gepirone produces downregulation of 5-HT_2 receptors, a characteristic shared by mechanistically distinct agents with antidepressant properties (Yocca et al. 1991). Furthermore, similar to SSRIs, continuous treatment with gepirone desensitizes dorsal raphe 5-HT_{1A} receptors, favoring enhanced serotonergic neuronal signaling (Blier and de Montigny 1987).

Gepirone is similar to buspirone in demonstrating activity in a variety of animal models that predict clinical effect for anxiety and depression. In preclinical anxiety models, gepirone was active in the rat Vogel conflict and open-field test (Stefanski et al. 1992), the rat social stress test (Tomatzky and Miczek 1995), the rat ultrasonic vocalization test (Cullen and Rowan 1994), and the rat fear-potentiated startle paradigm (Kehne et al. 1988). In depression models, gepirone has activity in several behavioral models, including learned helplessness (Giral et al. 1988; Martin et al. 1990) and the forced-swim test (Detke et al. 1995) in rats.

In a series of neuroendocrine studies in rodents and man (Anderson et al. 1990; Cowen et al. 1990), gepirone was observed to be similar to buspirone in that it significantly increases plasma levels of ACTH, β-endorphin, cortisol, prolactin, and growth hormone, accompanied by decreases in body temperature. The fact that prolactin levels are increased by gepirone, which lacks appreciable affinity for dopamine D_2 receptors, indicates that this prolactin effect of buspirone may result from multiple receptor interactions.

Pharmacokinetics and Disposition

Gepirone is well absorbed orally, with time to peak plasma concentration (T_{max}) approximately 1 hour. The T_{max} of gepirone is significantly delayed by food ingestion. Gepirone is subject to extensive first-pass metabolism (15% bioavailability), undergoing rapid biotransformation with a short plasma elimination half-life. Gepirone ER formulations have been developed, yielding significantly lower

maximum plasma concentrations (C_{max}) and longer T_{max} than gepirone (Timmer and Sitsen 2003). Gepirone ER once daily has a similar area under the curve (AUC) as the gepirone immediate-release preparation administered twice daily. C_{max} of the 1-PP metabolite of gepirone is significantly lower with gepirone ER administration, and the T_{max} is longer. Fluctuations in plasma gepirone concentrations are considerably less with gepirone ER than with the immediate-release formulation.

1-PP, one of two major metabolites of gepirone, possesses activity as a presynaptic α_2-adrenoreceptor antagonist but is thought to lack intrinsic antidepressant effects. Plasma concentrations of 1-PP exceed gepirone plasma levels (Tay et al. 1993) with extended-release formulations, although 1-PP levels are lower than with the immediate-release formulations.

The in vivo physiological effects exerted by gepirone may in part reside in 3-hydroxygepirone, which is an active metabolite of gepirone and has lower plasma concentrations with the ER preparation compared with the immediate-release formulation. It exhibits affinity and full agonist activity at the 5-HT_{1A} receptor (K_i = 58 nM) and antidepressant activity in preclinical models (Ward et al. 2000). Furthermore, and like gepirone, 3-hydroxygepirone inhibits the firing of dorsal raphe neurons and produces a desensitization of rat somatodendritic 5-HT_{1A} receptors after chronic exposure (Blier et al. 2000).

Indications and Efficacy

The immediate-release formulation of gepirone was extensively studied for a clinical indication in both the anxiety and depressive disorders. In a placebo-controlled trial comparing gepirone with diazepam in GAD, Rickels et al. (1997) found gepirone somewhat less effective than diazepam, with inferior tolerability and excessive dropouts. These results were consistent with those of other trials with the gepirone immediate-release formulation. Studies in depressive disorders with immediate-release gepirone indicated that it possessed antidepressant properties (Jenkins et al. 1990; McGrath et al. 1994; Robinson et al. 1989a).

Because of tolerability concerns with short-acting immediate-release formulations of gepirone, clinical development was switched to gepirone ER, with a major focus on treatment of MDD. Preliminary placebo-controlled studies provided evidence of the efficacy of gepirone ER in MDD (Feiger 1996; Wilcox et al. 1996). Feiger (1996) compared gepirone ER, imipramine, and placebo in an 8-week trial involving patients with DSM-III-R (American Psychiatric Association 1987) major depression. At dosages ranging from 10 to 60 mg/day, gepirone ER was significantly more effective than placebo treatment as measured by both the 17-item and 28-item versions of the Ham-D, with comparable efficacy to imipramine (150–300 mg/day). Gepirone ER was generally better tolerated than imipramine, with fewer anticholinergic and sexual side effects and with an adverse effect pattern typical of other azapirone agents, predominantly dizziness, light-headedness, and nausea.

A well-controlled efficacy trial comparing gepirone ER and placebo in MDD has been reported that demonstrates therapeutic benefit in the treatment of major depression (Feiger et al. 2003). In this 8-week trial involving 204 patients (gepirone n = 101, placebo n = 103), treatment with gepirone ER was initiated at a dosage of 20 mg/day and increased to 40 mg/day after 3 days; further dosage increase to 60 mg/day at week 2 was permitted if clinically indicated. Remission rates at week 8 were 24.8% for gepirone ER and 14.9% for placebo treatment (P <0.05). The CGI responder rates were 43.6% and 35.6%, respectively. With gepirone ER, 82% of patients experienced a treatment-emergent adverse event, whereas for placebo patients 56% experienced an adverse event. Ten patients (9.8%) and 3 patients (2.8%) on gepirone and placebo, respectively, terminated treatment prematurely due to adverse events. Based on results on the Derogatis Interview for Sexual Functioning—Self Report questionnaire (Derogatis 1997), there was no evidence that gepirone caused treatment-related sexual dysfunction. A second placebo-controlled trial of gepirone ER for treatment of MDD has been conducted, providing evidence for antidepressant effectiveness of gepirone (Bielski

et al. 2008).

In a 1-year relapse prevention study of the efficacy and tolerability for continuation treatment of major depression, gepirone ER was associated with a significantly lower relapse rate (23.0% vs. 34.7%) than placebo treatment (Keller et al. 2005). In a retrospective subgroup analysis of patients with significant anxiety symptoms associated with MDD, Alpert et al. (2004) reported gepirone ER to be superior to placebo treatment based on outcomes of several efficacy measures, including improvement in total scores on the Ham-D and global response rates.

Side Effects and Toxicology

Gepirone has a safety profile similar to that of buspirone, with dizziness, nausea, light-headedness, and insomnia the most commonly reported adverse events (Fitton and Benfield 1994). Treatment with gepirone ER, which has a lower incidence of side effects than the immediate-release formulation at therapeutic doses, is not associated with weight gain, sexual dysfunction, or sedation (Feiger et al. 2003).

CONCLUSION

Discovery of the 5-HT_{1A} receptor was instrumental in linking modulation of 5-HT neurotransmission to anxiety symptoms. Buspirone, a partial agonist of the 5-HT_{1A} receptor, is the first of a new class of antianxiety agents approved for treatment of GAD and anxiety with associated depressive symptoms. An ER formulation of gepirone, a more complete 5-TH_{1A} receptor agonist, has been shown to have antidepressant efficacy in several placebo-controlled trials. Clinical development of gepirone ER for indications in treatment of depression and anxiety disorders is ongoing.

Chapter 26. Putative New-Generation Antidepressants

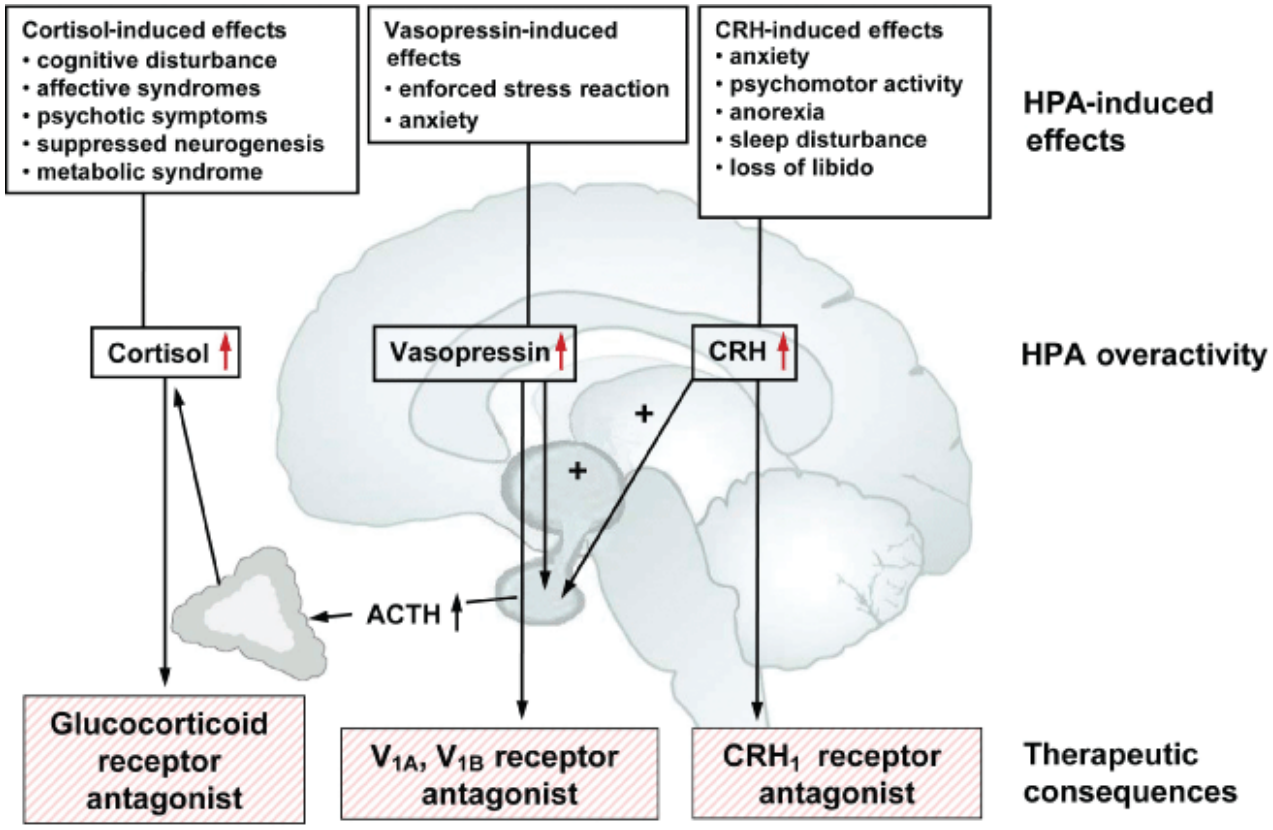
PUTATIVE NEW-GENERATION ANTIDEPRESSANTS: INTRODUCTION

For the past half-century, antidepressant development has been dominated by drugs that interfere with monoamine neurotransmitters. Some progress regarding safety and adverse effects is undeniable, and the increasing specificity of most current antidepressants targeting exclusively monoamines accounts for this improvement. Nevertheless, existing antidepressants exhibit limited efficacy and protracted onset of action, and we still do not know whether the pharmacological actions delineated thus far are those that account for the clinical benefits of these drugs in 60%–70% of patients with depression. Severe depression poses a particularly difficult problem, because failure to achieve clinical remission yields the risks of extended illness duration and chronicity (Nemeroff 2007). Elucidation of crucial steps in the mechanism of action of current antidepressants could yield an array of new drug candidates. The alternative route to developing better antidepressants relies on the increasing knowledge of the pathophysiology of depression emerging from clinical research and well-founded hypotheses derived from animal models. Despite huge research efforts by both academic and pharmaceutical industry investigators, none of the many discoveries of mechanisms involved in depression-related behavior has yet been translated into clinical application.

This chapter highlights some of the progress made, discusses the impediments to discovery of promising new drug candidates, and offers proposals for how an integration of systemic approaches and hypothesis-driven research may ultimately help us to identify and develop better antidepressants.

TARGETING THE STRESS HORMONE SYSTEM

In response to any kind of stress, the pituitary gland secretes adrenocorticotropic hormone (ACTH), which at the level of the adrenal cortex leads to increased synthesis and release of cortisol (corticosterone in rodents). Many research reports agreed that the key neuropeptides accounting for peripheral increase of stress hormones are corticotropin-releasing hormone (CRH; also known as corticotropin-releasing factor [CRF]) and vasopressin, both synthesized in specialized neurons in the hypothalamus (paraventricular nuclei), from which they reach the anterior pituitary via portal vessels. These neuroendocrine activities are closely associated with a large number of other neural projections resulting in neuropeptide release in many brain areas that were implicated in the neuroanatomy of depression and anxiety (de Kloet et al. 2005). Those extrahypothalamic structures include the central nucleus of the amygdala, the hippocampus, the locus coeruleus, and cortical structures such as the prefrontal cortex.



Also several vasopressinergic subsystems exist. One is particularly well characterized, as it consists of magnocellular neurons of the supraoptic and paraventricular nuclei from where axons project to the posterior pituitary eliciting secretion of vasopressin into the systemic circulation. Upon appropriate stimulation, this mechanism regulates a variety of physiological activities, including renal water absorption and hepatic glycogenolysis. More important in this context is a vasopressin subsystem inducing central release into brain areas that are considered to be involved in the pathogenesis of depression and anxiety. There, vasopressin elevations induce a number of behavioral responses to many stressors. Both neuropeptides, CRH and vasopressin, are involved in the adaptation to stress, as they elicit a number of behavioral responses that are suited to cope optimally with a threat. Over extended periods of time, however, these initially beneficial effects reverse into increased liability for anxiety- and depression-like behavior (Landgraf 2006).

There is good evidence from clinical research that both neuropeptides are elevated in depression. Such

evidence includes elevations of CRH and vasopressin in the cerebrospinal fluid (CSF) and increased expression of these neuropeptides in the brains (specifically the hypothalamus and prefrontal cortex) of depressed patients, as well as indirect evidence from neuroendocrine function tests (Scott and Dinan 2002). For example, if a patient with depression is treated with a low dose of dexamethasone, this results in suppression of ACTH, as the precursor of this hormone is negatively controlled by glucocorticoid receptors, to which dexamethasone binds. At the same time, the brain is deprived of the corticosteroid signal, since endogenous cortisol is decreased and cannot be replaced by dexamethasone, because at the low dosages used, this synthetic steroid does not enter the brain. This results in elevation of neuropeptide activation of the hypothalamic-pituitary-adrenal (HPA) axis aimed at reinstatement of appropriate corticosteroid levels. If dexamethasone-pretreated patients with depression receive a test dose of CRH, an excessive release of ACTH and cortisol occurs (Ising et al. 2006). It is assumed that this release is mediated by the induced elevation of vasopressin, which is normally negatively regulated by endogenous corticosteroids. As a result, the endogenously elevated vasopressin and the exogenously administered CRH amplify each other's effects at the level of the anterior pituitary to produce excessive ACTH and cortisol secretions. This finding is one cornerstone of the corticosteroid receptor hypothesis, which postulates that impaired intracellular signaling of steroid-activated hormone receptors (glucocorticoid receptors [GRs] and mineralocorticoid receptors [MRs]) results in inappropriately high and enduring secretions of CRH and vasopressin in the brain and of ACTH and cortisol in the periphery (Holsboer 2000). The stress hormone cortisol easily crosses the blood–brain barrier. Because a host of genes expressed in the brain are activated or suppressed by corticosteroids, mostly via regulatory response elements, it is not surprising that continuous overexposure of the brain to cortisol also produces behavioral changes (McEwen 2004). Such changes include labile, mostly depressed, mood. Similarly, depression is the most frequent psychopathology among patients with Cushing's syndrome, a disorder characterized by unrestrained hypophyseal–adrenal cortex activity. Another behavioral sequel of hypercortisolism is cognitive deficit, which is well known to be associated with depression. Other clinical features induced by hypercortisolism are suppressed hippocampal neurogenesis (see section "Enhancing Neogenesis of Brain Cells" later in this chapter) and the metabolic syndrome, both of which are frequent concomitants of severe major depression. Some depressed patients also show psychotic features. Since hypercortisolism (whether caused by a hormone-secreting tumor or by corticosteroid medications) also often produces psychotic features, it was hypothesized that the psychotic symptoms are mainly produced by corticosteroid excess (Schatzberg et al. 1985).

As a consequence of these abnormalities induced by various stress hormones, the potential role of stress hormones in the pathogenesis of depression has been hypothesized. Three complementary lines of pharmacological interventions are currently the focus of antidepressant drug discovery and development programs: glucocorticoid receptor antagonists, vasopressin receptor antagonists, and CRH receptor antagonists (Figure 26–1).

Activation of the hypothalamic-pituitary-adrenal (HPA) system results in elevation of corticotropin-releasing hormone (CRH), vasopressin, and cortisol, which produce several signs and symptoms of depression and anxiety. Blocking the actions of these neuropeptides at the receptor level provides a new lead for antidepressant and anxiolytic drug discovery. ↑ = increased.

Corticotropin-Releasing Hormone Receptor Antagonists

CRH exerts its actions through two different G protein–coupled receptors: CRH_1 and CRH_2. The two receptor subtypes are unequally expressed in the brain, where they bind not only to CRH but also to three other CRH-related peptides: urocortin I (UCN I), stresscopin-related peptide (also called UCN II), and stresscopin (UCN III). UCN I binds with equal affinity to both CRH_1 and CRH_2 receptors, while UCN II and III preferentially bind to CRH_2 receptors and have low affinity for CRH_1 receptors (Grigoriades 2005). The differential expression and function of CRH receptor subtypes in the brain holds particular relevance in regard to the question of whether CRH_1 receptors or CRH_2 receptors are preferred targets for drug interventions (Table 26–1).

CRH_1 Receptor Antagonists

As mentioned, a large number of studies using animal models clearly indicated that CRH accounts for many signs and symptoms of depression, including a host of stress-related features such as anxiety, sleeplessness, decreased appetite, decreased sexual interest, psychomotor agitation, and others. All of these findings were derived from studies that either injected CRH into the rodent brain and measured behavioral changes or used mice where CRH was overexpressed in the brain (Heinrichs and Koob 2004). That these behavioral effects of CRH can be targeted by interfering with CRH/CRH_1 receptor signaling was first shown with peptidergic CRH receptor antagonists (α-helical CRH [9–42], D-Phe-CRH [12–41], and astressin), which all were only poorly selective. Another line of evidence emerged from experiments that used antisense probes directed against CRH_1 receptor messenger RNA (mRNA), thus preventing translation into receptor proteins (Liebsch et al. 1999). These studies showed that the specific antisense probes resulted not only in reduced CRH but also in decreased stress-elicited anxiety-like behavior. Questions regarding specificity of effects by central peptide injections or antisense probes prompted the generation of mouse mutants where the CRH_1 receptor was deleted by genetic engineering, which confirmed the preeminent role of CRH_1 receptors (Smith et al. 1998; Timpl et al. 1998). The most compelling evidence came from a mouse mutant where the CRH_1 receptor was conditionally deleted, resulting in a functional CRH_1 receptor depletion restricted to the limbic system (Mueller et al. 2003). This finding was important, because in mutants where the CRH_1 receptor is also nonfunctional in the periphery (primarily the pituitary), the abnormal stress hormone regulation had to be considered as a potential confounder (Mueller and Holsboer 2006). This mouse model confirmed that CRH_1 receptors in the brain are responsible for anxiety-like behavior and supported that antagonism of CRH_1 receptor activity may provide a novel hypothesis-driven pharmacological strategy for treatment of stress-related disorders such as depression and anxiety.

A number of small nonpeptidergic molecules with good oral bioavailability and rapid penetration across the blood–brain barrier have been developed and tested in preclinical models of depression and anxiety. The inconsistencies of some of the test results can be ascribed to the fact that the animal models used were validated for the discovery of antidepressants acting at monoamine transmitter reuptake transporters (Markou 2005). This is exemplified by the recent observation that mice that overexpress CRH conditionally in the brain display hyperactivity when exposed to the forced-swim test (A. Lu et al. 2008), with enhanced struggling and reduced floating times. When treated with DMP-696, a selective CRH_1 receptor antagonist, struggling time decreased while floating increased. This observation is in opposition

to the behavioral changes observed in wild-type mice, which when treated with antidepressants exhibit decreases in floating relative to struggling (Markou 2005). In wild-type mice, where depression- or anxiety-like behavior is absent, most CRH_1 receptor antagonists produced reduced immobility similar to that observed after administration of monoamine-based antidepressants. The relevance of the affective state at baseline, which is now deemed pertinent for interpretation of drug effects on a stress-related behavior, is demonstrated in rat and mouse lines that have been selectively and bidirectionally bred for extremes in trait anxiety. As a result, rats and mice with high innate anxiety-like behavior as assessed on the elevated plus-maze are now available (Keck et al. 2001; Landgraf et al. 2007; Wigger et al. 2004). As illustrated in Figure 26–2, mice with innate high anxiety respond to the CRH_1 receptor antagonist DMP-696 with reduced anxiety-like behavior, again underscoring the importance of baseline behavior in the assessment of a drug's effects.

Mice selectively bred for high anxiety-like behavior (HAB) assessed on the elevated plus-maze show increased CRH expression in the PVN (not shown). When HAB mice are treated with a selective CRH_1 receptor antagonist, their behavior normalizes and becomes indistinguishable from that of mice with normal anxiety-like behavior (NAB). *Hatched bars* indicate pretreatment with the CRH_1 receptor antagonist DMP-696. Although a large number of small-molecule CRH_1 receptor antagonists have been discovered over the past 20 years, only a few of these have entered clinical development, and none has yet found its way to the market (Valdez 2006). A number of clinical trials are still under way, but few clinical data have yet been published. The first study reported was an open-label trial designed to assess the safety of R 121919 (also known as NBI-30775). This molecule binds specifically and with high affinity (K_i = 3.5 nmol/L) to cloned human CRH_1 receptors, can be orally administered, and crosses the blood–brain barrier easily. The excellent preclinical profile of this compound made it a preferred candidate for clinical development. The clinical evaluation was designed as an open-label trial to study safety and tolerability (Zobel et al. 2000). Additionally, changes in psychopathology scores, laboratory examinations, and sleep performance, including polysomnography, were recorded. The study population was split into equally sized groups that received either 5–40 mg/day (lower dosages) or 40–80 mg/day (higher dosages) over 30 days. As illustrated in Figure 26–3, in both dosage escalation panels, marked reductions in depression and anxiety

scores on patient and clinician scales were observed. The patient group receiving higher dosages showed markedly greater improvement. In fact, in the higher-dosage panel, 8 of 10 patients met the criterion of treatment response (i.e., ≤50% reduction in the Hamilton Rating Scale for Depression [Ham-D] baseline score), and 6 of 10 patients were classified as in remission (i.e., a Ham-D score of ≤8 points at study endpoint). In the low-dosage panel, only 5 of 10 patients were responders, and only 3 of 10 achieved remission. Any conclusions based on a small open-label trial are limited. Nevertheless, when the effect size obtained after a treatment period of 29 days was compared with that obtained from a control trial of the selective serotonin reuptake inhibitor (SSRI) paroxetine conducted over the same observation period under identical study conditions (Nickel et al. 2003), no significant differences between the two drugs were observed, which—within the inherent limitations of such an analysis—suggests that the clinical profiles of R 121919 and paroxetine are similar.

Two patient samples (*n* = 10 each) with severe major depression were treated with R 121919, a selective high-affinity CRH_1 receptor antagonist. Two different dosage escalation panels with weekly increases from 5–20 mg to 40 mg *(black lines)* and from 40–60 mg to 80 mg *(green lines)* were administered, resulting in significantly decreased severity scores on both depression (Hamilton Rating Scale for Depression [Ham-D]) and anxiety (Hamilton Anxiety Scale [Ham-A]) scales. Note that after cessation of active treatment, clinical worsening of depressive and anxiety symptoms was observed. CRH = corticotropin-releasing hormone 1 receptor.

Extensive laboratory examinations, including clinical chemistry and hematology, electroencephalography, and electrocardiography, failed to show any adverse effects of R 121919, regardless of dosage (Künzel et al. 2003). The drug's safety was also confirmed in an in-depth hormonal analysis of all endocrine systems in which it was demonstrated that the pituitary–adrenocortical response to an intravenously administered test dose of 100 µg human CRH was not affected by the drug (Zobel et al. 2000). This finding is of particular importance, because it confirms that even if a dose is administered that effectively blocks central CRH_1 receptors, there are still sufficient CRH_1 receptors available at the anterior pituitary corticotrophs that can be stimulated by CRH. Thus, the stress hormone system remains responsive to CRH, and treated patients do not develop drug-induced Addison's disease.

Disturbed sleep is a cardinal symptom of depression. Polysomnographic studies have demonstrated that patients with depression have increased rapid eye movement (REM) sleep density and decreased slow-wave sleep. The latter feature is reported to be induced by CRH in both animals and humans (Steiger 2007). A sleep electroencephalogram (EEG) analysis in a random subgroup of patients treated with R

121919 revealed increased slow-wave sleep and decreased REM sleep density (Held et al. 2004). The latter effect was more pronounced among patients receiving the higher dose of R 121919. These studies, as well as EEG studies in transgenic mice centrally overexpressing CRH, raise the possibility that the amount of REM sleep may serve as a biomarker identifying individuals with excessive central CRH secretion (M. Kimura [Max Planck Institute of Psychiatry, Munich], personal communication, July 2008). Despite these very promising early clinical results, further development of R 121919 was discontinued because of suspected liver toxicity at high dosages.

Another CRH_1 receptor antagonist, the nonpeptide tricyclic NBI-34041, was recently clinically investigated. This compound can also be orally administered, passes the blood–brain barrier, and binds to CRH_1 receptors with high affinity (K_i = 4.0 nmol/L). A randomized, double-blind, placebo-controlled study administered three different dosages of NBI-34041 (10, 50, and 100 mg/day) to 24 healthy male volunteers. The study was designed to evaluate whether the investigational drug would decrease the stress hormone response to a psychosocial stressor (Ising et al. 2007). For that purpose, the Trier Social Stress Test (TSST) was applied. The TSST is a standardized public-speaking procedure involving a mock job interview and performance of mental arithmetic (Kirschbaum et al. 1993). During and following the test paradigm, plasma ACTH and cortisol concentration–time curves were monitored. All subjects responded to the psychosocial stressor comparably in regard to tension or vigor required for achieving optimal performance (Dickman 2002). However, as illustrated in Figure 26–4, plasma ACTH and cortisol response was attenuated when the study participants were pretreated with NBI-34041. As was observed with R 121919, none of the administered drug dosages prompted a decreased release of plasma ACTH and cortisol in response to an intravenously administered test dose of CRH (Ising et al. 2007). The huge basic science database contrasts with the paucity of clinical reports using CRH_1 receptor antagonists. In fact, a number of unreported clinical trials were discontinued because of toxic side effects. Importantly, these adversities do not question the pharmacological principle of muting CRH/CRH_1 receptor signaling, as toxicity of investigational CRH_1 receptor antagonists was observed in tissues not carrying CRH_1 receptors.

Even after a CRH_1 receptor antagonist has cleared all of the hurdles required to enter the market, it remains undecided what the ultimate role of these agents in clinical practice will be. To establish a clinical differentiation against current antidepressants or new drugs that act at different pathways, at least two imminent questions must be addressed: 1) Do CRH_1 receptor antagonists act preferentially in patients with documented HPA axis hyperactivity? and 2) Are CRH_1 receptor antagonists best used as treatment alternatives to current antidepressants or as adjuncts to improve time to onset and remission rate?

Regarding the first question, the available data—although limited—suggest that current neuroendocrine HPA tests only poorly predict CRH_1 receptor antagonist treatment outcome (Zobel et al. 2000). In fact, from results both in transgenic mice carrying the CRH_1 receptor gene deletions and in depressed patients undergoing HPA tests, it can be concluded that disturbed central CRH/CRH_1 receptor signaling is not necessarily reflected by peripheral pituitary–adrenocortical measures (Mueller et al. 2003). Ideally, positron emission tomography (PET) quantification of central CRH_1 receptors with PET-active CRH ligands could yield biomarkers to identify patients who might benefit from such a treatment. It would come as no surprise if a number of clinical trials using traditional study designs would fail to demonstrate beneficial effects of CRH_1 receptor antagonists in depression and anxiety disorders. In the absence of biomarkers to identify patients with excessive CRH/CRH_1 receptor signaling, such studies will not be helpful in exploiting the beneficial effects of CRH_1 receptor antagonists, as they would leave unrevealed how many patients in the CRH_1 receptor antagonist group are indeed central CRH hypersecreters. PET studies using appropriate CRH_1 receptor ligands would be needed to identify patients who are potential CRH_1 receptor antagonist responders. As mentioned above, the possibility of using sleep EEG–derived REM sleep

measures to identify CRH hypersecretion deserves further study. The possibility that CRH_1 receptor antagonists might be well suited as adjunctive treatments is supported by a large number of studies showing that normalization of initially disturbed HPA axis activity underlies almost all antidepressant treatments, preceding the resolution of depressive symptoms (Ising et al. 2006). It may be worth testing whether the combination of an antidepressant and a CRH_1 receptor antagonist might offer an advantage over treatment with one or the other modality.

CRH_2 Receptor Antagonists

Much less effort has been devoted to evaluating the potential of CRH_2 receptor antagonists as drug targets. In fact, the physiological role of CRH/CRH_2 receptor signaling is less well elucidated, although several studies have demonstrated that this pathway is involved in stress response, cardiovascular function, and gastric motility. CRH_2 receptors seem to have a dual mode of action. In the acute (early) phase of stress, the CRH_2 receptor is activated through CRH and stresscopin (UCN III), increasing anxiety-like behavior. The CRH_2 receptor is also activated in the recovery phase, but in this phase it contributes to reduced emotionality (Hsu and Hsueh 2001). Three lines of CRH_2 receptor–deficient mice have been generated, which also failed to provide a clear picture regarding the behavioral response to blockade of CRH/CRH_2 receptor signaling. In two lines of CRH_2 receptor knockout mice, increased anxiety-like behavior was found (Bale et al. 2000; Kishimoto et al. 2000), but in the third line, no behavioral changes could be detected (Coste et al. 2000). A mouse line in which both CRH_1 and CRH_2 receptors were deleted was dominated by the effect of lacking CRH_1 receptors (Preil et al. 2001). Because no studies are available that use selective CRH_2 receptor antagonists, one can only speculate that such drugs may—through their action at the gastrointestinal tract—alleviate anorexia. Some drug companies are currently studying whether CRH_2 receptors are potential drug targets.

Vasopressin Receptor Antagonists

Given the clear indications that pharmacological interference with central vasopressin signaling pathways might be an alternative approach for treatment of stress-related disorders, surprisingly little research efforts aiming at vasopressin receptor antagonists have yet been reported. Three vasopressin receptor subtypes—V_{1A}, V_{1B} (often termed V_3), and V_2—have been cloned. Through V_{1B} receptors, found at the pituitary and central (mainly limbic) structures, vasopressin participates in regulation of the HPA axis by enhancing the release of ACTH and amplifying the action of CRH at corticotrophs (Gillies et al. 1982).

The relevance of this dual action has been demonstrated also in humans, where coadministration of vasopressin and CRH was shown to overcome dexamethasone-induced suppression of ACTH (von Bardeleben et al. 1985). Neither neuropeptide, when given alone, elicited substantial ACTH release (von Bardeleben et al. 1985). In contrast, dexamethasone-pretreated depressed patients show high ACTH release when CRH is administered. This was taken as a conjectural indication of increased limbic vasopressin production and secretion. Also, postmortem studies showed elevated vasopressin in the hypothalamus of depressed subjects (Purba et al. 1996). While V_{1A} receptors are expressed in the brain and are well documented to be involved in many stress-related behaviors (e.g., processing of social stimuli [Bielsky et al. 2005]), current pharmacological efforts are directed toward V_{1B} receptors (Serradeil-Le Gal et al. 2005). One compound, SSR-149415, a selective orally active V_{1B} receptor antagonist, may serve here as an example (Griebel et al. 2002). Recently, a rat strain was generated by selective breeding that shows high innate anxiety (Wigger et al. 2004). These animals overexpress vasopressin in both magnocellular and paraventricular hypothalamic nuclei (Keck et al. 2002). The reason for this overexpression is a polymorphism in the vasopressin gene promoter of these rats, resulting in impaired repression of gene activity (Murgatroyd et al. 2004). When treated with the SSRI paroxetine, the vasopressin gene expression was decreased in parallel with normalization of initially excessive HPA activity (Keck et al. 2003). Apparently existing drugs also interfere with the vasopressin system. From an alternative strategy (i.e., genetically engineered mice), a role for vasopressin V_{1B} signaling was suggested in the finding that V_{1B} receptor–knockout mice presented with reduced aggression and also changes in social recognition (Wersinger et al. 2002). These and other related findings led research at

Sanofi to develop SSR-149415 as a selective V_{1B} receptor antagonist (Griebel et al. 2002). This drug was capable of suppressing in a dose-dependent fashion the potentiating effect of vasopressin on CRH-elicited ACTH release. This effect was absent if a selective V_{1B} receptor antagonist was coadministered. Likewise, the stress hormone increases evoked by exposure of mice to the forced-swim test were reduced when the animals were pretreated with SSR-149415. The preclinical behavioral profile of SSR-149415 further indicated that this compound exerts anxiolytic activity in various firmly established test batteries (Serradeil-Le Gal et al. 2002). The results from standard behavioral screens for antidepressant drug candidates showed promising results. Of particular interest here was that the antidepressant-like behavioral changes induced by SSR-149415 were also observed in hypophysectomized rats, underscoring that the effects were not secondary to the neuroendocrine actions of the drug but through brain V_{1B} receptors, which are not linked to the stress hormone control. Because SSR-149415 and related compounds seem to have a favorable preclinical profile, including safety and tolerability in humans (Serradeil-Le Gal et al. 2005), we will soon learn whether V_{1B} receptor antagonists provide an alternative or complementary approach to existing antidepressants.

Glucocorticoid Receptor Antagonists

Rapid activation of the stress hormone system in response to a threat is essential for an individual's health, but equally important is the appropriate curtailment of stress hormone secretion (de Kloet et al. 2005). If this is not achieved and HPA activity remains elevated, a number of changes occur that range from cognitive disturbance, labile mood, and psychotic features to alteration in peripheral metabolism and immune defense. The sustained hyperactivity of the stress hormone system among depressed patients is reflected by hypersecretion of ACTH and cortisol at baseline and altered responses to a number of neuroendocrine function tests. An explanation of disturbed stress hormone regulation and its far-reaching effects on the development and course of depression is provided by the aforementioned corticosteroid receptor hypothesis of depression (Holsboer 2000). According to this hypothesis, signaling via corticosteroid receptors in the brain is impaired in depression. Two corticosteroid receptors are present in the brain—the GR and the MR, which usually form homodimers (GRGR, MRMR). Under certain circumstances, they also form heterodimers (GRMR), provided they are expressed in the same nerve cell, which occurs mainly in the hippocampus (Trapp et al. 1994). The GR is widely expressed in neurons and glial cells in limbic and cortical brain locations and has 10-fold lower affinity for cortisol (humans) and corticosterone (rodents) than the MR (de Kloet et al. 2005). Both receptors have important tasks in adapting to stressful stimuli. MR, which is already substantially occupied by cortisol under resting conditions, sets the thresholds at the onset of the stress response by determining the degree to which the CRH/CRH_1 receptor system gets activated. As a consequence, cortisol secretion is increased, which activates previously unoccupied GRs. On the behavioral side, this facilitates adaptation, promotes memory storage, and prepares coping. These behavioral changes via MR and GR, together with responses elicited from CRH and vasopressin receptors, are essential to adapt to the stressors (de Kloet et al. 2005). When sufficiently activated, GR suppresses further elevation of glucocorticoids via a number of negative feedback actions. At the same time, a huge number of genes in the brain are regulated by ligand-activated corticosteroid receptors. Prominent examples for these repressive effects of ligand-activated GRs are CRH, vasopressin, and brain-derived neurotrophic factor (BDNF). Given their postulated roles in the development and course of depression, it is obvious that impaired corticosteroid receptor function will have consequences not only for HPA activity but also for cognition, mood, and metabolic features, such as development of the metabolic syndrome. Since stress exposure is often a trigger for the onset of depression for patients with a susceptibility to depression, resilience would imply a high threshold for induction of CRH/CRH_1 receptor signaling. This threshold can be increased by increased MR (de Kloet et al. 2005). In this context, it is important to note that a number of studies have shown that the earliest detectable mode of antidepressant action is increased expression of MR, which is followed by increased GR (Herr et al. 2003; Reul et al. 1993). The clinical relevance of these experiments in rats is reflected by a study that administered spironolactone, an MR antagonist, in conjunction with antidepressant treatment and observed worsened clinical outcome (Holsboer 1999).

The opposing effects of GR and MR are further illustrated by studies with GR antagonists such as mifepristone (RU-486), which was reported to ameliorate psychotic symptoms in patients with Cushing's syndrome, a disorder characterized by unrestrained ACTH and cortisol secretion. A number of reports have suggested that mifepristone is also capable of mitigating psychotic symptoms in patients with psychotic depression (deBattista et al. 2006). This clinical condition is almost always associated with elevated plasma cortisol concentrations. Perhaps GR antagonists in combination with an antidepressant would be superior to standard treatment for psychotic depression, which currently combines neuroleptic drugs with antidepressants. This would be in line with a recent study showing that combination therapy with amitriptyline and haloperidol and monotherapy with trimipramine were equally effective in the treatment of psychotic depression (Künzel et al. 2008). Trimipramine is an antidepressant that effectively suppresses HPA activity (Holsboer-Trachsler et al. 1991).

Because mifepristone acts quickly and produces much fewer side effects compared with antipsychotic drugs, it would be desirable if this or another GR antagonist could provide an alternative to antipsychotics in the treatment of psychotic depression. Currently, several large controlled studies are under way, although no conclusive results are yet available. In particular, it will be crucial to ascertain whether positive response to mifepristone in combination with antidepressants is limited to those patients showing hypercortisolism. Indeed, the dopamine hypothesis of psychotic depression formulated by Schatzberg et al. (1985) suggested that this subtype is caused by a pathophysiology that is distinct from other forms of depression. Yet some questions need to be addressed by basic research, because it is not yet firmly established how GR antagonists may exert their beneficial effects on psychopathology. The possibilities range from suppression of stimulant effects of corticosteroids on dopaminergic neurotransmission, as suggested by Piazza et al. (1996), to neuroprotective effects (Crochemore et al. 2005; Mayer et al. 2006). The latter aspect is highlighted by studies that compared the effects of MR and GR on neuronal survival and again showed that MR and GR have opposing effects. In this context, it is of interest that rat hippocampal neurons exposed to amyloid β-protein (a cytotoxic peptide associated with plaque formation in brains of patients with Alzheimer's disease) are protected from cell death when treated with mifepristone (Behl et al. 1997).

Inhibitors of Glucocorticoid Synthesis

A crucial step in the biosynthesis of cortisol is the substitution of a hydroxyl group at the C11 position of ring C. This biosynthetic step is blocked by metyrapone, which inhibits this C11 hydroxylation by blocking the hydroxylating enzyme. Indeed, in small studies, metyrapone produced beneficial effects in depressed patients. In a double-blind, randomized clinical trial, metyrapone supplementation improved both time to onset of action and clinical outcome under two different antidepressants, nefazodone (a mixed serotonin [5-HT] reuptake inhibitor and 5-HT_{2A}/5-HT_{2C} antagonist) and the 5-HT reuptake inhibitor fluvoxamine (Jahn et al. 2004). Regarding the mechanism underlying this interesting observation, glucocorticoid-lowering effects may play a crucial role, but also the biochemical consequences of the enzyme block are to be considered under metyrapone treatment. In the absence of a negative feedback signal via cortisol, corticosteroids that are not hydroxylated at the C11 position are produced at a much higher rate as the adrenal gland becomes continuously overactivated by ACTH. The resulting high levels of 11-deoxycortisol and several other neurosteroids may also have favorable influences on affect and cognition via positive allosteric modulation of γ-aminobutyric acid type A ($GABA_A$) receptors by so-called neuroactive steroids (Rupprecht and Holsboer 1999).

AGOMELATINE

It has been observed that several chronobiological aspects are impaired among depressed individuals. These circadian fluctuations encompass body temperature, hormone secretory patterns, and sleep–wake cycle during depressive episodes, which normalize once a patient is remitted (Duncan 1996). Based on these longitudinal observations, it was hypothesized that these circadian changes are causally related to depression and that drug-enforced reinstatement may be a promising treatment modality. Melatonin produced in the pineal gland is the prototypical chronobiotic regulator of all these rhythms by acting via two distinct cell membrane–located receptors, MT_1 and MT_2. When these receptors are genetically deleted

in transgenic mice, behavioral changes are observed that resemble a depression-like phenotype (Larson et al. 2006; Weil et al. 2006). These and other related findings prompted the development of a drug that mimics the effects of melatonin at both MT receptors, and upon entering the brain, it would resynchronize altered chronobiological rhythms (Hamon and Bourgoin 2006). Agomelatine fulfills these expectations and acts as an agonist at MT_1 and MT_2 receptors. In addition, agomelatine is a 5-HT_{2C} antagonist. Several controlled clinical trials have confirmed the antidepressant efficacy of agomelatine (Kennedy and Emsley 2006). In one of these studies, 106 patients treated with agomelatine were compared with 105 patients receiving placebo, in an intent-to-treat population suffering from a major depressive episode and scoring on the 17-item version of the Ham-D with identical scores. At the end of the 6-week treatment period, agomelatine-treated patients had improvement from a score of 26.5 ± 2.8 to 14.1 ± 7.7, while placebo-treated patients improved from a baseline of 26.7 ± 3.0 to 16.5 ± 7.4 after 6 weeks. This difference of 15% was small but significant and was equivalent to reported drug–placebo differences observed in comparable studies (Thase et al. 2005). Apart from the favorable side-effect profile, two characteristics of agomelatine make this an attractive medication:

1. In depressed patients, agomelatine demonstrated sleep EEG changes consistent with the expectation of a 5-HT_{2C} receptor agonist (e.g., increased slow-wave sleep without affecting REM sleep). In addition, subjective sleep (onset and duration) and daytime alertness were improved as well (Kupfer 2006).
2. Antidepressant-related sexual dysfunction has received increasing attention given the association of SSRIs with diminished libido and difficulties in achieving orgasm (Clayton et al. 2002). In studies of agomelatine's effects on human sexual function, no agomelatine-induced sexual dysfunction was observed (Hamon and Bourgoin 2006). This is unsurprising, as it is known that melatonin exerts a facilitatory influence on sexual behavior.

The slight but significant superiority of agomelatine over placebo and its specific clinical profile, particularly the sleep-improving effects, seem to support the chronobiological diathesis of depression. However, it needs to be kept in mind that agomelatine is also a 5-HT_{2C} receptor antagonist, which may account for these clinical observations. As the anxiolytic actions of agomelatine are not prevented by melatonin receptor antagonists (Millan et al. 2005), it remains to be clarified which pharmacological action—MT receptor agonism or 5-HT_{2C} receptor antagonism—accounts for its psychotropic effects. Whatever the relative contribution of agomelatine's diverse pharmacological properties might be, this novel drug has a novel clinical profile and may provide a further argument that acting on different targets at the same time can be advantageous over highly specific compounds.

GLUTAMATERGIC SYSTEM

From recent investigations, evidence has emerged that glutamate and other amino acid neurotransmitters are involved in the pathophysiology and treatment of depression (Kugaya and Sanacora 2005; Paul and Skolnick 2003). Although not always conclusive, in vivo magnetic resonance imaging (MRI) studies have revealed altered glutamate levels in various brain areas (Auer et al. 2000; Sanacora et al. 2004), as well as in the CSF (Frye et al. 2007), of depressed patients. Also postmortem studies pointed to an abnormal glutamate receptor expression in the locus coeruleus and medial temporal lobe of depressed subjects (Beneyto et al. 2007; Karolewicz et al. 2004). Glial cells are of considerable importance in maintaining proper function of the glutamatergic system. Therefore, it is of interest that studies provided morphometric evidence for glial cell pathology in patients with depression, mainly in prefrontal cortical regions, which confirms glutamatergic abnormality in this clinical condition (Rajkowska et al. 1999). These findings were corroborated by more recent reports, which found decreased levels of glial fibrillary acidic protein (a glial marker) or reduced numbers of glial cells in the anterior cingulate cortex in the brains of subjects with major depressive disorder (Cotter et al. 2001).

Glutamate is the major excitatory neurotransmitter in the brain; it is ubiquitously present at high concentrations (8–10 mmol/kg) in brain tissue. In comparison, brain monoamine concentrations are in the micromolar range. The glutamatergic system plays a role in a wide area of functions, including learning and memory. The effects of glutamate are conveyed by ionotropic and metabotropic receptors located in pre- and postsynaptic neuron membranes as well as on glial cells. The removal of glutamate

from the synaptic cleft is achieved by an excitatory amino acid transporter (EAAT) located at neurons and glial cells. Given the relative abundance of glial cells over neurons, most of the glutamate clearance of synaptic clefts is by glial cell uptake. The EAATs are important in maintaining neuronal function, particularly in terminating the postsynaptic action of glutamate and reducing potentially toxic extracellular glutamate concentrations (Shigeri et al. 2004). If glutamate is not efficiently removed from the synaptic cleft, the continuous activation at postsynaptic ionotropic and metabotropic glutamate receptors may result in nerve cell death. In fact, these two glutamate receptor types also mediate glucocorticoid-induced apoptosis in hippocampal cells (J. Lu et al. 2003). Against this background, it is obvious that glial pathology, as observed in brains of depressed patients, may in conjunction with hypercortisolism account for the reported alterations of brain morphology. In fact, a number of studies showed that not only neurogenesis but also development of new glial cells is impaired by stressors, thus precipitating glutamate excess and cell death, ultimately rendering the brain susceptible to the development of mood disorders.

Based on the hypothesis that as a consequence of glial dysfunction, glutamatergic hyperactivity is one mechanism involved in the pathogenesis of depression, several glutamate receptor antagonists have been studied (Alt et al. 2005; Swanson et al. 2005b). Most studies used *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5 methylisoxazole-4-propionic acid (AMPA) receptor antagonists, which had been introduced as neuroprotectants in neurodegenerative diseases. Because some of these compounds also produced antidepressant-like behavioral changes in preclinical animal experiments, clinical trials were initiated to study their possible antidepressant effects. In fact, mood-elevating effects were reported from the NMDA receptor antagonists amantadine and D-cycloserine, which are used for other clinical indications (e.g., tuberculosis). Moreover, the β-lactam antibiotic ceftriaxone, which increases glutamate uptake via enhancement of glutamate transporter function, showed antidepressant-like properties in mice tested in a series of preclinical models predictive for antidepressants (Mineur et al. 2007). Also, the NMDA receptor antagonist ketamine showed antidepressant-like effects in several animal experiments, which is in line with a recently reported anxiolytic and antidepressant-like phenotype of mouse mutants, where NMDA receptor function was decreased by deletion of a crucial receptor subunit (Miyamoto et al. 2002).

In a randomized, double-blind, placebo-controlled study, a single dose of ketamine 0.5 mg/kg intravenously administered to patients with major depression was found to exert a rapid (2 hours postinfusion) and transient (1 week) antidepressant effect (Zarate et al. 2006a). While the clinical use of ketamine is limited because of its potential psychotomimetic effects, this study result will trigger development of other NMDA receptor antagonists and probe their postulated utility. Recently, also memantine, an NMDA receptor antagonist approved for the treatment of Alzheimer's disease, was studied regarding antidepressant effects (Zarate et al. 2006b). In a double-blind, placebo-controlled trial, 32 subjects with major depression were randomly assigned to receive memantine (2–20 mg/day) or placebo. In contrast to the study using ketamine, no treatment effect under memantine was observed. Possibly the low to moderate NMDA receptor affinity of memantine in comparison with ketamine may account for the observed discrepancy.

Also, AMPA receptors are considered a drug target for antidepressants, mainly because 1) positive allosteric modulators of AMPA receptors increase brain levels of BDNF and 2) AMPA receptor potentiators are active in rodent models predictive for antidepressant efficacy. It is not clear how AMPA receptor potentiation may achieve this effect, but it is remarkable that also current antidepressants such as SSRIs positively modulate AMPA receptors, supporting the view that interference with glutamate receptors —specifically, the AMPA receptor subtype—is a general mechanism of antidepressant action (Alt et al. 2005). There is little doubt that glutamate-acting drugs will become more important in future drug discovery and development of antidepressants. Their ultimate role is difficult to predict. It may be speculated that in accordance with the considerations made in the previous paragraphs, targeting only a glutamatergic mechanism is not appropriate for reinstating brain function in depression. Instead, monoaminergic and glutamatergic targets are to be modified in concert to achieve antidepressive effects. A recent study by Sanacora et al. (2007), in which riluzole, a drug that decreases glutamate release and

increases glutamate uptake, was added to ongoing antidepressant medication to 10 patients who had not responded to standard treatment, is of particular interest. In this pilot study, riluzole combined with standard antidepressants produced an antidepressant effect, suggesting a role for this drug as a potentiator of monoamine-mediated antidepressant effects.

Several candidate antidepressants and anxiolytics act on glutamate systems. For example, the dual-action serotonin–norepinephrine reuptake inhibitor milnacipran, launched as an antidepressant in Europe and recently approved for the treatment of fibromyalgia in the United States, is an AMPA receptor antagonist. The metabotropic glutamate 2/3 agonist LY544344 I is currently in development as an anxiolytic drug (Kellner et al. 2005). All other research programs, mainly targeting AMPA and NMDA receptors, are in early clinical development (Markou 2007).

NEUROPEPTIDES

Over the past 20 years, an impressive amount of data has been accumulated that indicates strongly that neuropeptides play a role as brain neurotransmitters. Many studies—ranging from administration of neuropeptides into specific brain areas of animal models to studies using interference RNA directed against mRNA of neuropeptides or their receptors to transgenic mice overexpressing neuropeptides or carrying corresponding null mutations of ligands and receptors—point to neuropeptide receptors as potential drug targets for the treatment of depression and anxiety disorders (Holmes et al. 2003). This approach is not limited to the neuropeptides related to the stress hormone system, as illustrated in a previous paragraph, but includes many other neuropeptides and their receptors. Some of these, considered to be of particular interest, are briefly reviewed here.

Substance P/Neurokinin 1 Receptor

More than 75 years ago, von Euler and Gaddum (1931) discovered an 11–amino acid peptide, called substance P, that proved to be the preferred ligand at the neurokinin 1 (NK_1) receptor. NK_1 receptors are highly expressed in the spinal cord, brain stem, and limbic system. Substance P was originally thought to be a mediator of pain, and the first NK_1 receptor antagonists were evaluated for their potential as analgesics. While these studies failed, a report by Kramer et al. (1998) demonstrated that the NK_1 receptor antagonist MK-869 (aprepitant) is indeed an effective antidepressant, superior to placebo and equal in potency to paroxetine. Unfortunately, a number of replication studies (e.g., Keller et al. 2006) produced mixed results, prompting most pharmaceutical companies to discontinue their NK_1 receptor antagonist programs. That is disappointing, because a number of clinical and basic studies strongly supported the theory that blockade of the substance P/NK_1 receptor signaling cascade may represent a novel antidepressant mechanism. For example, substance P was found to be elevated in patients with depression and to increase in response to stress (Geracioti et al. 2006). This is in agreement with reports of decreased central NK_1 receptors in depression (Stockmeier et al. 2002). If substance P is administered centrally to animals, a number of behavioral changes are induced that resemble anxiogenic and depressogenic response patterns, including not only behavioral but also cardiovascular and other vegetative changes (Stout et al. 2001). In agreement with these observations are findings obtained from substance P– and NK_1–knockout mice, which showed reduced anxiety- and depression-like behavior (Bilkei-Gorzo and Zimmer 2005). Despite some disillusionment regarding the utility of NK_1 receptor antagonists in clinical practice, the chapter does not seem to be closed on these agents, and a recent report on the efficacy and safety of a novel compound, L759274, supports this view (Kramer et al. 2004).

Galanin

Galanin, a 30–amino acid neuropeptide, is widely distributed in the central nervous system, where it exerts its action via three receptor subtypes: Gal_1, Gal_2, and Gal_3. Norepinephrine (NE) neurons in the locus coeruleus as well as 5-HT neurons in the dorsal raphe nucleus can synthesize galanin, and in vivo microdialysis studies suggested that galanin plays an important role as a modulator of NE and 5-HT release (Z. Q. Xu et al. 1998; Yoshitake et al. 2004). A relationship to mood, anxiety, and stress response was derived from studies that injected galanin into the rat brain and observed anxiolytic effects (X. Lu et al. 2005). Also a study that administered galanin to depressed patients and measured psychopathology

and recorded the sleep EEG reported antidepressant-like effects (Murck et al. 2004). Further support comes from investigations that administered antidepressants and found that they activated galanin expression in the dorsal raphe nucleus. Studying individual galanin receptors, current antidepressants seem to shift galanin neurotransmission from a predominant galanin/Gal_3 receptor pathway toward a galanin/$Gal_{1,2}$ receptor signaling. These observations suggested that the Gal_3 receptor is a potential drug target. In fact, several Gal_3 receptor antagonists (e.g., SNAP 37889 and SNAP 398299) have been developed and are currently under investigation (Swanson et al. 2005a). Alternatively, stimulating Gal_1 or Gal_2 receptors is also an option. Accordingly, a potent, highly selective Gal_2 receptor agonist, galmic, which is orally available and passes the blood–brain barrier, was synthesized (Ceide et al. 2004). At present it is difficult to predict whether modulators of Gal receptors will play a role in future drug development. If so, they may be used to enhance the effects of the monoamine-based antidepressants.

Orexigenic Peptides

Body weight is regulated by a homeostatic control system in which the brain—in particular, the hypothalamus—senses and integrates incoming signals and coordinates appetite by releasing orexigenic neuropeptides. Among these, at least three—melanin-concentrating hormone (MCH), neuropeptide Y (NPY), and orexin—have been linked to the pathogenesis of depression. Subsequently, their signaling pathways have been investigated to identify potential drug targets.

Melanin-Concentrating Hormone 1 Receptor Antagonists

MCH is a 19–amino acid polypeptide mainly produced in the lateral hypothalamus, where projections to many brain areas originate. The effects of MCH in humans are mediated via two G protein–coupled receptors: MCH_1 and MCH_2. Because of MCH and MCH_1 receptor expression in frontal cortical regions, nucleus accumbens, dorsal raphe nucleus, amygdala, and hippocampus, this system has primarily been studied in the context of depression (Shimazaki et al. 2006). In mice, where the MCH_2 receptor does not exist, MCH overexpression is associated not only with increased feeding behavior but also with a depression-like phenotype. In agreement, MCH_1 knockout mice showed decreased anxiety-like and depression-like behavior. In line with a depressogenic effect of MCH are neuropeptide-induced elevations of HPA activity via increased CRH secretion and enhanced anxiety- and depression-like behavior in several behavioral tests. Likewise, an MCH_1 receptor antagonist (GW-3430) blocked the neuroendocrine and behavioral effects of MCR only in wild-type mice, but not in mice where the MCH_1 receptor was deleted (Smith et al. 2006). These and other complementary studies prompted the development of MCH_1 receptor antagonists, and several compounds are currently characterized.

SNAP-7941 is a high-affinity antagonist ligand for the MCH_1 receptor and proved to be a centrally active anorectic compound that, according to long-term observations in animals with diet-induced obesity, may serve as an antiobesity drug, since it produced a sustained and consistent decrease in food consumption and body weight. In extension of these studies on food intake, SNAP-7941 was also tested in behavioral paradigms predictive of antidepressant- or anxiolytic-like effects. The results from these experiments provided strong support for the MCH_1 receptor as a regulator of mood (Borowsky et al. 2002). It is not yet clear whether these depressogenic and anxiogenic effects are mediated by MCH-induced activation of CRH/CRH_1 receptor pathways. Studies in which MCH is administered to CRH_1 receptor knockout mice or mice pretreated with a CRH_1 receptor antagonist would help to clarify this issue. Currently, several pharmaceutical companies are developing MCH_1 receptor antagonists (e.g., ATC0065, ATC0175) that have shown anxiolytic- and antidepressant-like activity in mice and rats (Chaki et al. 2005). Recently, another MCH_1 receptor antagonist (SNAP-94847) has been described that has an anxiolytic- and antidepressant-like profile that is clearly distinct from that of current antidepressants (David et al. 2007; Roy et al. 2007). If the antidepressant-like effect in combination with the anorectic effect of MCH_1 receptor antagonists could be translated into a clinical medication, it may be particularly useful for those patients whose depression is characterized by reduced activity and weight gain, often termed atypical depression. Also, some psychotropic drugs (e.g., mirtazapine, olanzapine, but also some SSRIs) increase body weight in some patients. These would benefit from coadministration of an MCH_1 receptor antagonist.

Neuropeptide Y Receptor Agonists

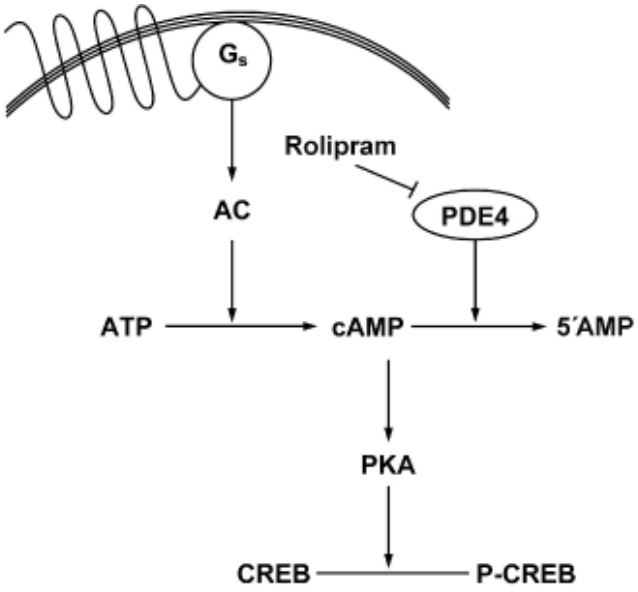
Neuropeptide Y is a 36–amino acid polypeptide that is abundantly present in many brain areas, including the locus coeruleus (where it is coexpressed with NE), hippocampus, hypothalamus, amygdala, nucleus accumbens, and neocortex. Actions of NPY are mediated in the brain via three different G protein–coupled receptors: Y_1, Y_2, and Y_5. Some clinical data point to decreased activation of NPY/$Y_{1,5}$ signaling in patients with depression (Redrobe et al. 2002), which agrees with findings from animal experiments showing that activation of Y_1 and Y_5 receptors in the amygdala produces anxiolytic-like effects (Kask et al. 2002; Primeaux et al. 2005; Sajdyk et al. 2002). The link between NPY and mood has also been confirmed by studies demonstrating increased anxiety-like behavior in NPY-null mutant mice (Palmiter et al. 1998). In addition, transgenic rats overexpressing NPY in the hippocampus demonstrate a remarkable resilience toward stress exposure (Vezzani et al. 1999). The mechanism underlying the stress-buffering effects of NPY remains to be elucidated. Possibly NPY potentiates the anxiolytic effects of GABA and inhibits glutamate release. Whether the pharmaceutical industry will pursue the development of NPY receptor agonists, specifically Y_1 or Y_5 agonists, is yet not clear.

Orexin Receptor Antagonists

Orexin-A and orexin-B (also named hypocretin 1 and hypocretin 2) are two neuropeptides produced by a cluster of neurons in the posterior lateral hypothalamus. They were originally implicated in the control of food intake (Samson and Resch 2000). The orexin neurons innervate many brain regions that drive arousal and attention, including the locus coeruleus (where noradrenergic projections emerge) and the dorsal raphe nucleus (from which serotonergic projections emerge). These neuroanatomical findings and the corresponding distribution of orexin receptors (OX_1 and OX_2) triggered research efforts investigating other effects than feeding behavior. Most interest has been attracted by findings that orexin/$OX_{1,2}$ signaling is involved in behavioral activity, wakefulness, arousal, and attention (Kilduff and Peyron 2000). The role of orexin as a major component of sleep–wake regulation has been strongly supported by findings in patients with narcolepsy. Patients suffering from this sleep disorder have excessive daytime sleepiness, episodes of muscle weakness (cataplexy) triggered by emotional stimuli, and intrusive REM sleep. These patients have degenerated orexin-producing hypothalamic neurons and decreased orexin in the CSF (Mignot et al. 2002; Nishino et al. 2000; Thanickal et al. 2000).

These findings stimulated the search for drugs that block orexin/$OX_{1,2}$ signaling, and the effects of the first $OX_{1,2}$ receptor antagonists in rats, dogs, and humans were recently reported (Brisbare-Roch et al. 2007). Administration of ACT-0788573, an orally available tetrahydroisoquinoline derivative that readily passes the blood–brain barrier, was found to decrease alertness, without signs of cataplexy. These behavioral effects were uniform in all three species tested. In the sleep EEG in rats, both REM and non-REM sleep were increased, and in human volunteers, a shortened latency to stage 2 sleep was recorded during a daytime nap opportunity. In the absence of an all-night polysomnography, no conclusion about whether $OX_{1,2}$ antagonists restored physiological sleep patterns can be drawn. When compared with 10 mg zolpidem, a short-acting nonbenzodiazepine $GABA_A$ receptor modulator, the orexin receptor blocker had a longer duration of action. ACT-0788573 produced fewer side effects in comparison with zolpidem. This first report of a single dose administered to healthy volunteers does not allow one to predict whether this new class of drug might also be effective for long-term administration in patients suffering from insomnia. However, given that disturbed sleep is a cardinal symptom among depressed patients, coadministration of an $OX_{1,2}$ receptor antagonist might be a worthwhile strategy. This possibility is particularly compelling because some antidepressants preferentially prescribed to improve sleep (e.g., mirtazapine) also tend to increase body weight. Orexin$_{1,2}$ receptor antagonists are devoid of such adverse effects and, on the contrary, may help maintain body weight.

TARGETING SIGNALING PATHWAYS



Phosphodiesterase Inhibitors

By inhibiting presynaptic monoamine reuptake transporters, antidepressants enhance activation of

postsynaptic G protein–coupled receptors to which NE and 5-HT selectively bind. In response to ligand binding, the receptor, when coupled to a stimulatory G protein (G_S), activates the enzyme adenylate cyclase, which results in increased cyclic adenosine monophosphate (cAMP) levels. Most of the effects of cAMP are mediated by activation of protein kinase A (PKA). One of the downstream targets of PKA is CREB (cAMP response element binding protein), which is believed to play a key role in antidepressant-induced mechanisms (Nestler et al. 2002). The activation of CREB via phosphorylation is a mechanism common to nearly all antidepressants, once they were chronically administered. Antidepressants also upregulate expression of CREB, and several studies link CREB expression and activation to antidepressant treatment response, possibly via expression of BDNF, whose gene activity is in part regulated by binding of phosphorylated CREB. In the light of this hypothesized mechanism, elevated levels of cAMP are essential to promote this action.

cAMP is degraded by a phosphodiesterase (PDE) into adenosine monophosphate (Figure 26–5). cAMP is a ubiquitous second messenger, responsible for a multitude of physiological functions, which involve activation of transcription factors by phosphorylation. Not surprisingly, the inactivation of cAMP by PDE is complicated. To date, 11 families of PDEs have been identified, which generate 30 different isoforms that are able to degrade cAMP (Houslay and Adams 2003). The PDE4 family has received particular attention, because over 20 years ago a PDE4 inhibitor, rolipram, had been discovered and developed by Schering Pharmaceuticals (Wachtel 1983). Rolipram was shown to be an inhibitor of cAMP-specific PDE4. Members of this PDE subfamily are encoded by four PDE4 genes, which encode over 16 different isoforms. In animal models as well as in small clinical trials, rolipram was demonstrated to exert antidepressant effects (Fujimaki et al. 2000; Hebenstreit et al. 1989). Its side-effect profile, particularly nausea and vomiting, prompted discontinuation of its clinical development.

Rolipram inhibits phosphodiesterase inhibitor 4 (PDE4), thus preventing degradation of cAMP into systems of 5'AMP and enhancing phosphorylation of transcriptional factors (e.g., CREB via protein kinase A [PKA]). 5'AMP = adenosine-5'-monophosphate; AC = adenylate cyclase; cAMP = cyclic adenosine monophosphate; CREB = cAMP response element binding protein; G_S = stimulatory G protein.

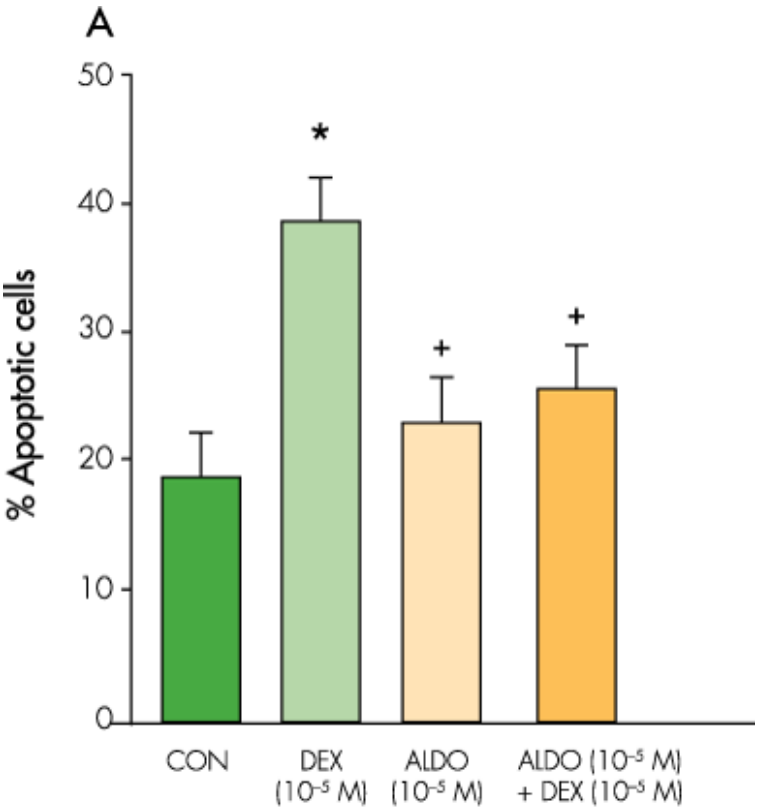
The interest in PDE4 inhibitors, however, is still alive, and a growing body of research focused on neurobiology of depression and antidepressant mechanisms may ultimately result in an upsurge of novel PDE4 inhibitors. One possible way of using this unique mechanism would be elucidation of the brain

area–specific expression of the four PDE4 subtypes (PDE4A–D), for which, as mentioned before, multiple isoforms exist. Based on the hypothesis that activation of CREB by phosphorylation in the hippocampus is an important common pathway of almost all antidepressants, it would be useful to know whether a specific PDE4 subtype exists in this brain area that is different from the PDE4 subtypes in areas that mediate nausea and vomiting. Recently a transgenic mouse model for emesis was studied, where either PDE4B or PDE4D genes were deficient (Robichaud et al. 2002). This study concluded that inhibition of the PDE4D subtype mediates the emetic side effects observed under rolipram. Interestingly, the PDE4D subtype is predominantly expressed in the area postrema, known to be involved in emesis.

The new possibilities available in pharmaceutical industry to develop assays for very specific potential targets, that allow screening of huge compound libraries, will hopefully result in new lead compounds selectively inhibiting those PDE4 subtypes that are directly involved in the antidepressant effects of this class of drugs (Zhang et al. 2002). Such discovery programs can possibly capitalize on the recent disclosure of the crystal structure of PDE4B complexed with rolipram (R. X. Xu et al. 2004).

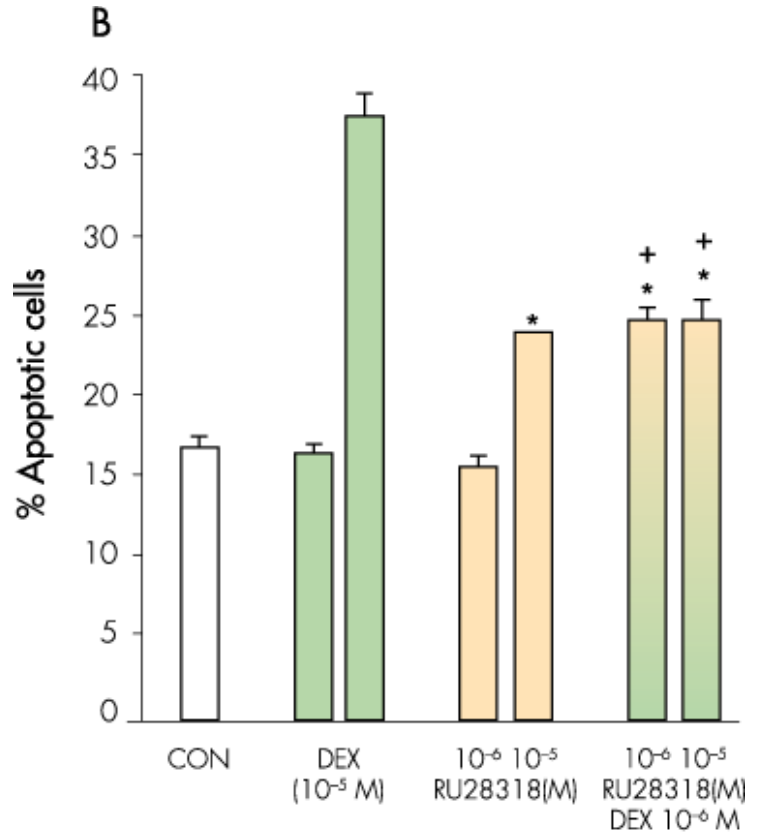
Glycogen Synthase Kinase–3 Inhibitors

The search for targets of mood-stabilizing lithium salts led to glycogen synthase kinase–3 (GSK-3), and more recently, preclinical evidence implicates modulation of GSK-3 in the mechanism of action of mood stabilizers (Gould and Manji 2005) and current antidepressant medications (Eldar-Finkelman 2002). GSK-3 is found as two isoforms, GSK-3α and GSK-3β, that have a 97% sequence homology and also have similar biological effects. GSK-3 is a kinase that is ubiquitously expressed in the brain and is involved in many signaling pathways. The best elaborated pathways comprise Wnt signaling, insulin signaling, and neurotrophic signaling (Gould et al. 2006). Lithium was found to decrease GSK-3 at therapeutic dosages, and the effect of GSK-3 inhibition was shown in vivo by increase of β-catenin, which acts as a cellular transcription factor and is inactivated by GSK-3. After the role of lithium salts in GSK-3 was documented, the effects of antidepressants on this kinase were also studied. In fact, some preliminary data support the view that the antidepressants fluoxetine and imipramine both exert inhibitory effects on GSK-3 in the prefrontal cortex (Li et al. 2004). A considerable amount of supporting evidence from cellular studies resulted in testing GSK-3 inhibitors in animal models predictive for antidepressant action. For example, intracerebral injection of the GSK-3 inhibitor L803 in mice produced increased struggling and decreased floating in the forced-swim test (Kaidanovich-Beilin et al. 2004). Similar results were obtained with AR-A014418, another selective GSK-3 inhibitor (Gould et al. 2004). In this study, the drug not only reduced immobility in the forced-swim test but also decreased spontaneous as well as amphetamine-induced activity. The latter behavioral paradigm is used as a predictor for antimanic-like effects. Indeed, the pharmaceutical industry is currently developing a number of novel GSK-3 inhibitors, and it will not take long until a first drug candidate will undergo validation.



ENHANCING NEOGENESIS OF BRAIN CELLS

A number of MRI studies have reported smaller hippocampal volumes in patients with depression (Sheline et al. 1996; Videbech and Ravnkilde 2004). These findings were related to the duration of depression and depression-associated hypersecretion of cortisol (Mirescu et al. 2006). Indeed, many experiments suggested that excessive corticosteroid secretion endangers hippocampal neurons by increasing their vulnerability to noxious agents such as excitatory amino acids and oxidative stress (Behl et al. 1997; Sapolsky 2000). A current hypothesis posits that decreases in hippocampal neurons render an individual susceptible to pathological stress response (i.e., development of a stress-related disorder) and that antidepressants reverse this deficit by enhancing neurogenesis (Nestler et al. 2002). They do so by activating the cAMP–PKA pathway that results in phosphorylation of CREB, which is a transcription factor that when activated binds to the promoter of the gene coding for BDNF and enhances expression of this neurotrophic factor (see above). Brain levels of BDNF are also reduced in the prefrontal cortex and hippocampus of depressed patients who had committed suicide (Dwivedi et al. 2003). In contrast, patients who had been treated with antidepressants showed normal hippocampal BDNF concentrations (A. C. Chen et al. 2001). Likewise, altered plasma BDNF concentrations were reported in affective disorders (Machado-Vieira et al. 2007; Shimizu et al. 2003), although the source of this neurotrophin in



blood remains to be elucidated. A role for BDNF has also been demonstrated in animal models, where injection of BDNF into rat hippocampi produced antidepressant-like effects (Shirayama et al. 2002). On the other hand, a study that used an inducible cell-targeted knockout system demonstrated that forebrain BDNF is necessary for antidepressant-induced behavioral changes in the forced-swim test (Monteggia et al. 2004). The neurogenesis hypothesis of depression and antidepressant mode of action is attractive in many ways, as it submits that the brain—originally regarded as a postmitotic organ—can produce new cells. Furthermore, this hypothesis is in line with a protracted time to onset of antidepressant action. A report by Santarelli et al. (2003) concurred that neurogenesis accounts for antidepressant effects in mice. These researchers exposed mice to X rays targeting hippocampal stem cells, thus preventing neurogenesis. These mice failed to show the fluoxetine-induced behavioral changes otherwise observed with this and other antidepressants. These interesting experiments, however, do not allow one to conclude that any antidepressant-like activity necessarily requires neurogenesis, but they do shed some light on possible antidepressant cellular targets. For example, a recent study by Encinas et al. (2006) suggested that amplifying neural progenitor cells are the sole target of fluoxetine among the neurogenic cells in the adult nervous system. These authors emphasize the drug-induced changes in neurogenesis and the eventual increase in new neurons that follow this effect on early progenitor cells. In fact, the results of a recent study indicate that the ability of (four distinct) antidepressant drugs to reverse learned helplessness and anhedonia in a rat model of depression does not depend on ongoing neurogenesis (Bessa et al. 2008); in that study, neurogenesis was blocked with a powerful antimitotic agent.

Studies aiming at the mechanism by which antidepressants may induce neurogenesis or act as neuroprotectants have focused on drug-induced CREB activation, which in turn promotes BDNF production (Blendy 2006). However, CREB is not essential for the effect, as antidepressants can also induce the characteristic behavioral changes in CREB-null mutants (Conti et al. 2002). The corticosteroid receptor hypothesis may offer an alternative explanation, as the postulated impairment of GR- and MR-mediated effects in depression have clear-cut consequences for neuronal cell survival (de Kloet et al. 2005; Holsboer 2000). Glucocorticoids, through their action of GR, promote cell death via apoptosis, an effect that is counteracted by the MR agonist aldosterone (Crochemore et al. 2005). Likewise, GR-induced cell death is exacerbated by MR antagonists (Figure 26–6). Thus, MR activators function as neuroprotectants, counteracting the effects of corticosteroids mediated by GR, which also act as suppressors of BDNF. In this light, it is of note that antidepressants are activating MR gene expression and by this mode of action may not only protect nerve cells from apoptosis but also promote neurogenesis (Herr et al. 2003; Reul et al. 1993). For the pharmaceutical industry, the challenge is to identify drug targets that promote MR signaling without disturbing electrolyte homeostasis. Possibly, it is necessary to modulate specific proteins that stimulate MR-mediated gene transcription such as FAF-1 (Obradovic et al. 2004). Alternatively, the proapoptotic effects of corticosteroids acting via GR can be blocked with GR antagonists. Mayer et al. (2006) showed that mifepristone (RU-486, a GR antagonist that also blocks progesterone receptors) reinstates corticosterone-reduced neurogenesis in the hippocampus of adult rats. At this point, the field awaits more specific drugs capable of directly interfering with intracellular corticosteroid receptors to restore MR/GR balance, thus normalizing not only HPA axis activity but also cognitive performance, neurogenesis, and stress resilience, by altering the threshold at which CRH and vasopressin secretion is triggered. As mentioned above, this threshold is determined by the amount and function of hippocampal MR in relationship to GR. CRH_1 receptor and vasopressin V_{1B} receptor antagonists are also known to enhance generation of new neurons, and similar effects were reported for rolipram (Alonso et al. 2004; Duman et al. 1997).

Perhaps not yet sufficiently appraised is the role of glial cells in the antidepressant-induced effects in the brain. Given the fact that glial cells outnumber neurons by as much as 10 to 1 in some brain regions, these cells deserve more attention as drug targets. Probably antidepressants have profound yet unrecognized effects on glial cells. For example, Hisaoka et al. (2007) recently reported that antidepressants increase glial cell line–derived neurotrophic factor (GDNF) expression and release from glioma cells. These effects were independent from antidepressant effects on monoamines. That glial cells are affected in depression was demonstrated by Rajkowska et al. (1999), who found lowered glial cell counts in certain areas of the frontal cortex in postmortem brains of depressed subjects. Furthermore, serum GDNF concentration is decreased in depressed individuals, but it is not entirely clear from where this neurotrophic factor derives. Other studies have confirmed reductions of oligodendrocytes in the amygdala. This brain area plays a key role in fear and anxiety, and glial deficits may have significant effects on the function of neural circuits believed to be impaired in depression. The observed volume changes in various brain areas of patients with depression represent not only neuronal loss (or, more likely, decreased neurite branching) but also a substantial decrease of glial cells. GDNF may restore these deficits by inducing both glial genesis and neurogenesis (Y. Chen et al. 2005).

These examples of antidepressant actions on trophic factors and their possible implication for neogenesis of both neurons and glia further highlight that many mechanisms quite remote from those related to monoamine reuptake inhibition need to be considered for further antidepressant drug discovery. In the case of neurotrophic factors, it is of note that their receptors, once activated, induce a manifold of diverse effects that are also brain region specific. For example, as mentioned above, infusion of BDNF into the hippocampus induces antidepressant-like effects (Shirayama et al. 2002), while the same treatment in the ventral tegmental area–nucleus accumbens reward system produces the opposite effect (Eisch et al. 2003). Thus, stimulating BDNF in general may eventually produce counteracting effects, which necessitates targeting the BDNF/TrkB pathway via modulators that influence the signaling cascade in a brain area–specific manner.

SYSTEMATIC GENETIC APPROACHES

Current research aiming at new investigational antidepressants is now following two different approaches. One is based on the current hypothesis of pathogenesis of depression and mounting data about antidepressant actions other than monoamine reuptake transporter blockade. The second line of research uses information from genetic studies that attempt to identify genes that confer risk for human depression. The method used today for the latter approach is genomewide association studies, which entail the matching of a given human genome sequence with an annotated high-resolution map of common genetic variations. In complex disorders such as major depression, genetic risk factors are likely to be associated with moderate risk. Once such a risk factor is present in a population, it may account for a substantial proportion of that population's cases. If a genetic variant is present in a gene, its functional characterization is warranted. It may direct us toward novel targets for medical intervention.

This is exemplified in two related studies that identified in two large populations of bipolar and unipolar depression a mutation in the gene coding for the purinergic receptor P2X7 (Barden et al. 2006; Lucae et al. 2006; McQuillin et al. 2008). This receptor is activated by adenosine triphosphate (ATP) and is expressed in brain neurons and glial cells (microglia and astrocytes). The function of the P2X7 receptors in the context of depression is not clear. What is known is that this receptor is involved in Ca^{2++}-independent glutamate release (Duan et al. 2003). The mutation found is resulting in an amino acid exchange in the intracellular loop of the receptor, changing its function when ATP is stimulated. Once

it is established that these functional changes are required for increased susceptibility to develop stress-related depression-like changes in animal models, molecules will be developed that compensate for this functional deficit. As this receptor is cell membrane located, such a strategy seems feasible. It is of note that here again, both types of brain cells—neurons and glia—contain this potential drug target in their cell membrane. More genomewide association studies will come, providing a large number of potential drug targets. Very recently, Baum et al. (2007) conducted a genomewide analysis in a bipolar cohort and found a mutation in the first intron of a gene encoding diacylglycerol kinase eta, a key protein in the lithium-sensitive phosphatidyl pathway. Once these human genetic findings have been replicated in large confirmation studies, they will be validated according to their possible functional consequences. If these analyses point to impairment of signaling between brain cells, strategies will be developed aiming at drugs that restore the functional change. This drug discovery process will ultimately result in personalized medicines that are based on an individual patient's genotype, which includes genes conferring risks for disease. As discussed below, this strategy has only a chance to be translated into bona fide clinical applications if genotyping is complemented by dynamic biomarkers (Holsboer 2008).

Another systematic approach is the use of animal models that respond to current antidepressants and a subsequent analysis of all gene transcripts that were up- or downregulated by this treatment (Landgrebe et al. 2002; Sillaber et al. 2008; Yamada et al. 2005). This approach may result in a large number of candidate genes possibly involved in antidepressant mode of action. The hypothesis behind this strategy is that identification of pathways that are close to the crucial mode of action may ultimately lead to discovery strategies, which attempt to target these pathways more directly.

Several caveats need to be considered. One is that studying current antidepressants in these models may not lead to new mechanisms. Another problem arises from the fact that regulation of genes in healthy mice is not necessarily identical to the situation in human patients, thus making validation of the findings in mice inevitable. It is of note that gene homology across species does not preclude that gene regulation differs. Finally, there is as yet no animal model for studies of depression and antidepressant action. The forced-swim test, for example, has been validated with tricyclic antidepressants. Using the same behavioral paradigm to screen for antidepressant drugs that modulate different pathways may generate attrition of worthwhile candidates just because of an inappropriate animal model (A. Lu et al. 2008). Most of these tests are based on stress exposure. While it is undisputed that stressors can trigger depression, it is also widely accepted that stress alone does not precipitate depression if there is no genetic disease susceptibility. Early childhood trauma has been shown to be a particularly important stressor (Heim and Nemeroff 2001), but many often subtle genetic variations are also needed to render an individual at risk. Thus, a healthy animal that is exposed to stress is certainly not a homologous model for human depression.

What is needed are animal models in which genetic variants, as found in genomewide association studies in human depression, are inserted into the mouse genome. If these mice, carrying one or several mutations that confer risks for depression in humans, are exposed to stressors and change their behavior accordingly, they would constitute much better models for studies of antidepressant action. The minimum requirement for studies examining how antidepressants modify gene expression profiles in the mouse brain is that these mice show behavioral responses that mimic some of the core symptoms of depression. In fact, genotype-dependent activities were shown to determine the response to antidepressants in mice (Cervo et al. 2005). Systematic approaches using genomewide human genetic analysis or microarray chips in order to identify antidepressant-induced changes in gene activity may ultimately result in unprecedented drug targets.

FUTURE DIRECTIONS

In his famous article on imipramine from 1961, which also contained the first pharmacogenetic considerations, Jules Angst stated: "The basis for the antidepressant effect of imipramine has not yet been elucidated, although more than three years have passed since its introduction" (Angst 1961, p. 381). Today, 50 years after the first reports on antidepressant drug effects of the tricyclic imipramine and despite huge efforts from both academic and industrial research, we still do not know by which

mechanism antidepressants exert their clinical effects.

Although the psychopharmacology of depression and anxiety disorders is still dominated by monoamine hypothesis–based antidepressants, an impressive amount of knowledge on antidepressant-related mechanisms other than monoamines has accumulated. As this chapter demonstrates, none of the clinical and basic science discoveries has resulted in one single non-monoamine-system-based treatment for depression.

In the past, the development of more specific drugs directed against a limited number of targets had positive consequences with regard to side effects. Nevertheless, even specific SSRIs, such as paroxetine, exert considerable NE reuptake inhibition after prolonged administration (Gilmor et al. 2002; Owens et al. 2001). Moreover, once the 5-HT receptor is blocked by SSRIs, accumulating 5-HT can act as a false transmitter in dopamine neurons (Zhou et al. 2005). These findings of limited selectivity within the monoamine system raise the question of whether drug discovery strategies for complex diseases such as depression would benefit from therapeutics directed toward many targets from the beginning. The current searches that follow the one-disease, one-target, one-drug paradigm ignore the network complexity and pathway redundancy that are engineered into the brain through evolutionary processes. The new era of antidepressant discovery will depart from the search for a single chemical substance interacting specifically with a single molecular target. The new approach will be based on systems brain pathology where multiple targets are hit by multiple drug components. The multicomponent therapeutics are either single molecules activating or deactivating multiple sites or combinations of several different drugs. The current new candidates derived from nonmonoamine systems—such as stress hormones, neuropeptides, and glutamate-related drugs—or those modifying signaling pathways will therefore be most likely administered in combinations.

The decision of which combination an individual patient will receive will be based on his or her individual risk or disease profile constructed from genetic and dynamic biomarkers. It is common clinical knowledge that a specific drug that had worked in a patient's previous depressive episode may not be equally effective in current and future episodes. Apparently, disease-related and environmental factors in combination with the genotype have altered the protein pool (Kitano 2007). Such changes are secondary to epigenetic modifications that lead to remodeling of chromatin and subsequent changes in gene expression (Tsankova et al. 2007). In fact, preliminary evidence exists that chronic stress via epigenetic regulation results in suppression of BDNF while antidepressants can interfere with this epigenetic mechanism and bring BDNF levels in the hippocampus back to normal. A recent study by Miller and Sweatt (2007) suggested that covalent binding of a methyl group to cytosine, which can occur when cytosine is followed by guanine, is a crucial step in memory formation. DNA methylation is a hallmark of epigenetic modification.

Both genetic variants and interacting environmental factors continuously shape an individual's protein pool. As antidepressants bind at proteins and act through proteins, it is unsurprising that they exert different actions under different conditions. Therefore, laboratory information is warranted to obtain information of an individual's risk or disease profile at a given time. Such information can be obtained from panels of biomarkers that include genetic, proteomic, and also pathophysiological information. Recent research has suggested that a variant in the 5-HT transporter gene, the 5-HT_{2A} receptor gene, predicts response to an SSRI (McMahon et al. 2006). Moreover, a polymorphism in the gene encoding a cochaperone, FKBP5, an intercellular protein critically involved in glucocorticoid receptor signaling, was reported to be a genetic marker predicting response to antidepressants of all kinds (Binder et al. 2004). As this study has now been replicated (Lekman et al. 2008), the question arises of whether this protein constitutes a drug target. Such questions can now be addressed using appropriate assays and chemical compound libraries. Other gene variants that can determine treatment outcome either are well established (e.g., those coding for drug-metabolizing enzymes [Kirchheiner and Seeringer 2007]) or are currently being validated (e.g., ATP-binding cassette transporters [Hermann and Bassetti 2007] coding for P-glycoproteins that influence brain penetrance of antidepressants [Uhr et al. 2000, 2008]). Uhr et al. (2008) used transgenic mice in which the *ABCB1* gene for P-glycoprotein was deleted to identify which

antidepressants are P-glycoprotein substrates (i.e. have hampered access to brain tissue). In the clinical portion of the study, the investigators examined whether the presence of an *ABCB1* mutation that weakens the extrusion-pump activity of P glycoprotein affects patient response to antidepressants that are P-glycoprotein substrates. In fact it was demonstrated that decreased P-glycoprotein function due to an *ABCB1* gene mutation was associated with improved clinical response among patients treated with antidepressants recognized by P-glycoprotein as substrates. This finding led to the use of *ABCB1* genotyping to guide drug selection and dosing.

While protein marker validation for treatment of depression is yet not accomplished, neuroendocrine tests show some promise. For example, a large number of studies have shown that the normalization of initially exaggerated stress hormone responses to a combined dexamethasone/CRH test after 2–3 weeks of antidepressant treatment predicts favorable outcome (Ising et al. 2007). Probably this test can be used as a biomarker that is closely related to the clinical phenotype, as such representing convergence of many different causal mechanisms. Biomarkers will become indispensable not only for clinical practice but also for drug development of candidate antidepressants. If a biomarker is validated in large patient samples to predict antidepressant treatment outcome, any new drug candidate can be studied in several clinical trials according to its effect on the dynamic biomarker. Biomarkers will become especially important with the advent of personalized medicines that include genotypes. It is still difficult to predict whether a drug that specifically targets a functional alteration generated by a genetic polymorphism will also work in patients not carrying this particular gene variant. Given the steady influence of environmental and disease-related factors on the quantitative composition of proteins, future personalized medicines will encompass identification of both genetic variants conferring disease risks and biomarkers, providing an individual patient's personal molecular signature and functional profile at a given time point (Holsboer 2008).

The field is facing exciting changes: the pharmaceutical industry's reluctance to adopt a biomarker-assisted personalized pharmacotherapy model reflects its fear that this approach will lead to the demise of the blockbuster model, which is broken anyway. The high number of current discontinuations of late-stage drug developments, patent expirations, and declining new drug approvals are sobering facts that should call for a strategic change. Genotype- and biomarker-assisted identification of subpopulations and subsequent development of drugs targeted to these patients could be the key to the industry's future success. Such a strategy might even be capable of reviving drugs that had previously failed in clinical trials. It might also help to revive drugs that were withdrawn from the market or whose development was put on hold because of adverse effects in a few patients who would a priori have been excluded from trials if their biomarker risk profiles had been analyzed. Most importantly, for the sake of the patients, the current situation in antidepressant treatment could be substantially improved if joint research efforts would result in abandonment of a reductionist "one size fits all" magic bullet approach in favor of an individualized approach based on genotype- and biomarker-assisted multicomponent therapy.

movements (later labeled *tardive dyskinesia*) came from France in 1959. The pervasiveness and significant adverse consequences of short-term and long-term motor side effect classic antipsychotic drugs led to a search for antipsychotic drugs that would be as efficacious but without the risk of EPS.

Clozapine, a dibenzodiazepine synthesized in 1959, was the first antipsychotic drug without EPS (i.e., atypical). It was first

Aliphatic Phenothiazines

The aliphatic phenothiazines share a dimethylamide substitution at their tenth carbon. Chlorpromazine (Thorazine or Largactil) is the prototypical member of this class and rema phenothiazine most widely used throughout the world. With a chlorine atom attached to its second carbon, chlorpromazine is heavily sedating because of its high level of antich -adrenergic, and antihistaminergic actions.

Piperidine Phenothiazines

Piperidine phenothiazines are named for the presence of a piperidine ring at their tenth carbon. Although members of this group have similar efficacy and side effects compared phenothiazines, they are notable for having a less potent effect on nigrostriatal dopamine$_2$ (D_2) receptors and a higher level of anticholinergic activity; consequently they are as lower frequency of EPS. Thioridazine (Mellaril) and its metabolite, mesoridazine (Serentil), are the only piperidines available within the United States. The use of these agents ha extinguished by a black box warning about significant QTc prolongation that was added to their product label in 2000.

Piperazine Phenothiazines

With a substitution of a piperazine group at the tenth carbon of a phenothiazine, the piperazines have greatly increased D_2 blockade and a lower affinity to muscarinic, α-adrene histaminergic receptors. Some of the most potent conventional antipsychotics available in the United States, including fluphenazine (Prolixin), perphenazine (Trilafon), and trifl (Stelazine), belong to this class. The well-known antiemetic prochlorperazine (Compazine) is also part of this class; although approved for the treatment of psychosis, it is rarely antipsychotic.

Thioxanthenes

Structurally and pharmacologically similar to the phenothiazines, the thioxanthenes also differ widely in their pharmacological profiles based on similar side-chain substitutions For instance, chlorprothixene shares the same dimethylamide and chloride substitution as chlorpromazine, with which it also shares its pharmacological profile. Thiothixene (Na piperazine side chain and a strongly electrophilic substitution [$SO_2N(CH_3)CH_3$], thus sharing the pharmacological profile of the piperazines. Of further interest, the thioxanthene from the phenothiazine ring by having a carbon atom at its tenth position, has two optically active isomers, or enantiomers. Of the two isomers of the ring, the *cis* isomer exerts dopaminergic receptor blockade than the *trans* isomer.

Butyrophenones

The butyrophenone class has a piperidine ring with a three-carbon chain ending in a carbonyl-substituted p-fluorobenzene ring. Butyrophenones differ on the basis of the subst within their piperidine rings (see Figure 27–1). Haloperidol, arguably the best-known classic antipsychotic, is the most widely used member of this class. Sharing a similar phar but having a lower level of activity within the nigrostriatal pathway, another phenothiazine, droperidol, is available only in an intramuscular form for the indication of nausea. Bo droperidol are strong dopamine receptor antagonists and show little antimuscarinic, antihistaminergic, and antiadrenergic activity. Although widely used in the past as an antips is approved by the FDA only for use as an antiemetic, and its use has recently declined due to its QTc-prolonging effects.

Spiperone, one of the most potent dopamine antagonists in existence, is utilized as a D_2, dopamine$_3$ (D_3), and dopamine$_4$ (D_4) receptor radiolabel for research purposes exclusi

Dibenzoxazepines

Loxapine, the only FDA-approved agent within the dibenzoxazepine class, is composed of a tricyclic ring structure with a seven-member central ring. It has a piperazine side ch position R2 (see Figure 27–1). It exhibits an intermediate level of D_2 blockade, as well as some serotonin$_2$ (5-HT_2) antagonism. Its side-effect profile is characterized by interm autonomic effects. Loxapine has the distinction of being the most "atypical" of the classic antipsychotics because it is structurally similar to the dibenzodiazepine clozapine. Ano feature of loxapine is that one of its metabolites, amoxapine, is marketed as an antidepressant with antipsychotic effects.

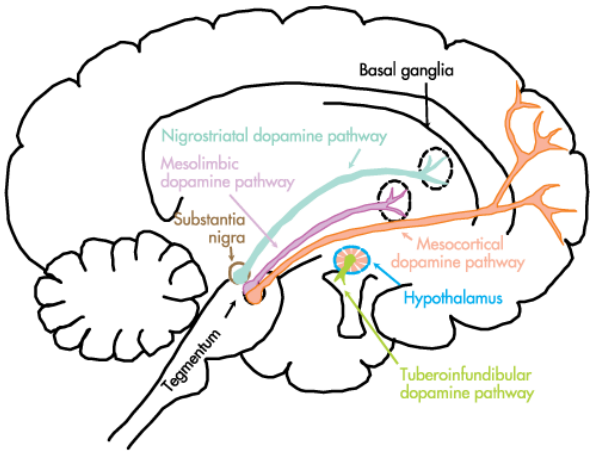
Dihydroindoles

Molindone is the only member of the dihydroindoles available in the United States. Sharing a similar structure with the indoleamines (see Figure 27–1), such as serotonin, molin distinction of being the only classic antipsychotic not associated with any weight gain or a lowering of the seizure threshold.

Diphenylbutylpiperidines

Pimozide, the only agent within the diphenylbutylpiperidine class available in the United States, is approved only for the treatment of Tourette's syndrome and has the distinctio highest selectivity and potency for dopamine D_2 receptors among the conventional antipsychotics. It significantly prolongs the QTc interval, and this has limited its utilization. D benperidol, pimozide shares many characteristics of the butyrophenones (see Figure 27–1).

Benzamides and Iminodibenzyl Agents



Sulpiride, the prototypical substituted benzamide, is a relatively selective dopamine D_2 antagonist and lacks significant activity on cholinergic, histaminergic, or noradrenergic r of this relative selectivity and a lower propensity to cause EPS, sulpiride is one of the more common classic antipsychotics utilized in Europe (e.g., it was utilized in about half th

to receive an FGA in the CUtLASS study). Structurally related to metoclopramide, sulpiride has also been used for the treatment of peptic ulcer and vertigo. No classic antipsycho either the benzamide or the iminodibenzyl classes is available in the United States.

PHARMACOLOGICAL PROFILE

The classic conventional antipsychotic drugs have a multitude of effects on various physiological variables through their antagonistic actions on different neurotransmitter syste antipsychotic effects of these agents are believed to occur primarily through antagonism of D_2-type dopaminergic receptors. Historically, blockade of D_2 receptors was believed for the treatment of psychosis, although the efficacy of weak D_2 blockers such as clozapine called this theory into question at one time. The major therapeutic, as well as advers antagonism have been conceptualized in the context of the major dopaminergic tracts present in the brain, which include the mesocortical, mesolimbic (A10), tuberoinfundibula nigrostriatal (A8 and A9) tracts (Figure 27–2).

Although the effects of D_2 blockade on the mesocortical and mesolimbic dopaminergic systems are believed to represent the putative mechanism of action of conventional antips blockade of these tracts is also believed to result in a number of adverse cognitive and behavioral side effects. Such side effects are frequently observed in both animals and hu such side effect is *ataraxia,* a state of relative indifference to the environment leading to behavioral inhibition and diminished emotional responsiveness. Inhibition of conditione other learned behaviors is observed in rodent models. Although operant-conditioned reward-seeking behaviors are diminished in rat models, one notable exception is the relativ cocaine self-administration. One might argue that this correlates with reported anhedonia in human subjects, as well as an increase in cocaine abuse often present within the hu treated with conventional antipsychotics. D_2 receptor antagonism in the mesocortical dopaminergic pathway leads to a blunting of cognition (bradyphrenia) and avolition–apath referred to as the ***neuroleptic-induced deficit syndrome***—that can be difficult to differentiate from the primary negative symptoms of schizophrenic illness itself. Although conve antipsychotics exhibit a robust "tranquilizing" action, they do not induce a state of coma or anesthesia even at very high doses.

Blockade of the tuberoinfundibular tract projecting to the hypothalamus and pituitary gland results in multiple neuroendocrine side effects processed through the pituitary gland dopamine is involved in enhancing the release of most pituitary hormones, it is actually responsible for the tonic inhibition of prolactin release. With significant dopaminergic blo tuberoinfundibular tract, prolactin release is no longer prevented, and the release of other pituitary hormones is no longer enhanced. High levels of prolactin combined with decr follicle-stimulating hormone and luteinizing hormone often result in amenorrhea, galactorrhea, gynecomastia, decreased bone density, impaired libido, and erectile dysfunction.

High levels of D_2 dopaminergic blockade within the nigrostriatal system, which projects to the basal ganglia and caudate, produce some of the most undesirable side effects of c antipsychotics. Movement disorders and EPS such as akathisia, resting tremor, rigidity, and hypokinesia were once believed to be necessary "evidence" of a therapeutic antipsy However, the advent of the new-generation antipsychotics that are associated with minimal EPS conclusively dispensed with this misconception. At higher levels of D_2 blockade, observe a generalized dystonia, catalepsy, and a rigid, immobile catatonic state that may be accompanied by waxy flexibility.

Classic antipsychotic agents have varying degrees of activity at serotonergic, cholinergic, noradrenergic, histaminergic, and other nondopaminergic receptors. Although it is unc these activities contribute to or interfere with their efficacy in the treatment of psychotic symptoms, they clearly result in a variety of adverse effects. Because of differences in pharmacological activity of different classic antipsychotic agents at these receptors, there are predictable differences in their side-effect profiles.

PHARMACOKINETICS AND DISPOSITION

Generally, the pharmacokinetic profiles of the conventional antipsychotics remain poorly understood. Many hundreds of potential metabolites remain undiscovered, even for som extensively studied agents. The physiological activity of several metabolites has also not been precisely defined. However, several general statements can be made concerning t antipsychotics as a group.

Administration and Absorption

Many of the conventional antipsychotics are available in both oral and intramuscular formulations. Although relatively common in the past, intravenous usage of the parenteral f chlorpromazine, and other antipsychotics is not FDA approved. Oral administration of the conventional antipsychotics results in adequate but variable absorption. Calcium-conta antacids, coffee, and heavy nicotine use may decrease absorption from the gastrointestinal tract. Peak plasma levels with oral preparations are generally reached in 1–4 hours, being reached slightly more rapidly with liquid concentrates. All of the agents are highly lipophilic, leading to increased distribution in brain tissue relative to plasma. Oral prepa extensively metabolized in the liver during their first pass through portal circulation by undergoing any number of transformations, including glucuronidation, oxidation, reducti methylation. Steady-state levels are reached in a period of four to five times the half-life of the drug in question.

Intramuscular administration results in faster, more predictable absorption, with peak plasma levels in 30–60 minutes and clinical efficacy as rapidly as 15 minutes. With intram intravenous administration, plasma levels may be as high as four times those of the oral route because of circumvention of the hepatic first-pass metabolism.

Although 10 classic antipsychotics are available in a long-acting (depot) formulation around the world, haloperidol and fluphenazine are the only antipsychotics currently availa formulation in the United States. Although fluphenazine was the first antipsychotic to be released in a long-acting form as an enanthate ester, the longer-lasting decanoate form haloperidol and fluphenazine later became more popular secondary to a lower frequency of side effects. In a decanoate preparation, the antipsychotic drug is esterified to a lipi suspended in sesame oil. The injection is administered into a major muscle, and the drug is slowly released to the bloodstream through the oil over time. As the esterified versio diffuses into other tissues, the ester chain is hydrolyzed, resulting in the smooth release of the drug in question. This results in the smooth and progressive release of these long between scheduled injections. Fluphenazine decanoate can be given every 2–3 weeks on the basis of its half-life of 7–10 days, while haloperidol decanoate may be given every of its longer half-life. These preparations require from 3 to 6 months (four to five times the half-life) to reach steady-state levels and are eliminated slowly from the body, with p concentrations detectable for many months after discontinuation of the drug. Their bioavailability relative to oral administration is twofold greater.

Distribution

Most of the conventional antipsychotics are highly protein-bound (85%–90%). This feature is of importance when other highly protein-bound medications are used concomitant risk of increasing levels of free or unbound drugs into the toxic range. The antipsychotic drugs are highly lipophilic, which allows unbound portions of the drug to readily cross t barrier with concentrations twofold higher in the brain than in the peripheral circulation. The drugs also readily cross the placenta to the fetus in pregnancy. The lipophilic prope also allow for large amounts of the drugs to be stored in bodily tissues (i.e., fat, lungs, liver, kidneys, and spleen), leading to high apparent volumes of distribution, generally in

range. This property prevents them from being removed from the body effectively via dialysis in cases of overdose.

Metabolism

The conventional antipsychotics are metabolized in the liver by hydroxylation and demethylation to forms that are more soluble and readily excreted by the kidneys and in the fe compounds undergo further glucuronidation and remain active as dopamine receptor antagonists. Because of the many active metabolites of the antipsychotic agents, it has not obtain meaningful correlations between plasma levels and clinical response. Factors such as age, genetic variability among individuals, and coadministration of other drugs caus diverge widely (10- to 20-fold) among individuals.

The majority of conventional antipsychotics are metabolized by the cytochrome P450 (CYP) enzyme subfamilies. Since 2D6 is important for the metabolism of many of these anti variation in the rate of 2D6 metabolism should be considered, especially since most conventional antipsychotics inhibit 2D6 as well. It is estimated that 5%–10% of Caucasians medications through the CYP2D6 pathway, and a higher proportion among African Americans as well. Ultrarapid 2D6 metabolizers have been described in other populations. CYI subfamily enzymes are also involved in the metabolism of some classic antipsychotics, and this may be relevant to understanding drug–drug interactions of those agents.

Excretion

The major routes of excretion of the classic antipsychotics are through urine and feces by way of bile. These drugs are also excreted in sweat, saliva, tears, and breast milk. Elim varies from 18 to 40 hours for these drugs. Lower doses of antipsychotics are generally needed in elderly patients because of decreased renal clearance. Because of the long eli of these agents, once-a-day dosing is possible for each of these agents following stabilization.

MECHANISM OF ACTION

Initial hypotheses centered on the role of dopamine as the major factor in the pathophysiology of psychosis. Carlsson and Lindqvist (1963) first demonstrated an increase in dop following antipsychotic administration. This increase was shown to be a result of dopaminergic blockade, resulting in an increased rate of turnover. Reserpine reduces dopamine blocking the uptake and storage of dopamine into synaptic vesicles by inhibiting the vesicular monoamine transporters (VMATs). Amphetamine intoxication served as a drug-ind positive symptoms of schizophrenia. Drugs that blocked dopaminergic receptors, specifically the D_2 receptor, were noted to have greater efficacy and potency as antipsychotics dopaminergic agonists exacerbate psychosis and dopaminergic blockade treats it, dopamine has held central importance in our conceptualization of the neuropharmacology of s Initially, dopamine turnover appears to be increased, as measured by an increase in central nervous system (CNS) metabolites such as homovanillic acid. It is thought that ultim result when this trend is reversed by subsequent receptor supersensitization and ultimate decreases in dopaminergic turnover. The time course of the antipsychotic effect of the that both the initial and persistent dopamine D_2 receptor blockade and the more gradually developing depolarization blockade are relevant to antipsychotic action.

The contrast between the efficacies of promazine and chlorpromazine lies in chlorpromazine's tighter affinity to the D_2 receptor. Although structurally related to chlorpromazine its weak binding to the D_2 receptor, resulted in poor antipsychotic efficacy beyond mere sedation. However, although chlorpromazine is more potent than promazine, it remains potent D_2 receptor antagonists. A 100-mg dose of chlorpromazine is roughly equivalent to 5 mg of trifluoperazine and 2 mg of haloperidol. The potency of a classic antipsychotic its affinity for the D_2 receptor. High-potency agents with the greatest D_2 affinity are utilized in single-digit total daily doses, whereas low-potency agents are utilized in triple-di doses.

As additional antipsychotic drugs were developed, the goal of minimizing the sedative, anticholinergic, and autonomic side-effect profiles common among lower-potency antipsy the development of drugs that more potently block D_2 receptors, such as the butyrophenones. EPS were considered a sign of therapeutic antipsychotic dosage by early clinicians realize the serious impact on the patients of long-term EPS associated with excessive D_2 blockade. Decades later, positron emission tomography (PET) data revealed that a D_2 re of 65%–70% correlates with maximal antipsychotic efficacy, with prolactin elevation appearing beyond 72% D_2 occupancy and EPS appearing beyond 78% D_2 occupancy witho benefits at higher rates of occupancy. Despite the fact that classic antipsychotic agents have been utilized in the treatment of schizophrenia and other psychotic disorders for ov is still unclear if this 65%–70% occupancy has to be continuously maintained or intermittently achieved (tight versus loose D_2 receptor binding). The importance of 5-HT_{2A} bloc amelioration of EPS was later incorporated into the design of the SGAs discussed elsewhere in this text (see Chapters 28, 29, 30, 31, 32, and 33).

INDICATIONS AND EFFICACY

Schizophrenia and Schizoaffective Disorder

Conventional antipsychotics are best known for the treatment and maintenance of the psychotic (also known as positive) symptoms of schizophrenia. The major putative mecha D_2 blockade of the mesolimbic and mesocortical tracts. In many individuals, this blockade results in a measurable decrease in the positive symptoms of schizophrenia, including delusions, and behavioral disorganization. However, negative and cognitive symptoms of schizophrenia respond less robustly. In fact, they may be worsened by blockade of me that play roles in cognition and hedonic reinforcement.

The failure to improve the negative symptoms of schizophrenia is one of the major drawbacks of the classic antipsychotics. In fact, the EPS induced by the FGAs can worsen neg symptoms by inducing bradykinesia and bradyphrenia. Another major limitation is the lack of improvement of positive symptoms (i.e., refractoriness) in about 25% of schizophr partial response (i.e., treatment resistance) in another 25%. The discovery that clozapine is more effective than classic antipsychotics in treatment-refractory patients and is de EPS and tardive dyskinesia led to the introduction of the SGAs. Six additional SGAs (risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, and paliperidone) have been i United States, and they have almost completely supplanted FGAs because of their presumed greater efficacy and better safety/tolerability. However, the greater costs of SGAs, their benefits were not being realized consistently, and the realization that most of our recent information about these agents derives from industry-sponsored clinical trials (the often contain discrepancies) led to the implementation of two large-scale government-sponsored studies in the United States (CATIE) and the United Kingdom (CUtLASS) betwe Although findings of both of these studies indicate an absence of any greater effectiveness of SGAs over FGAs on preliminary review, a closer examination of the study samples provides additional insights about how classic and atypical antipsychotics might compare (Table 27–2).

In phase I of CATIE, 1,460 patients with schizophrenia were assigned to treatment with either an FGA (perphenazine) or one of four SGAs (risperidone, olanzapine, quetiapine, and duration of treatment on the originally assigned medication was assessed over an 18-month period. After control for important variables, no differences in rates of all-cause between perphenazine and various SGAs were noted; in fact, no significant differences were observed with reference to symptomatology, cognition, social function, or motor sic of CUtLASS, 227 patients with psychotic illness (75% of patients with schizophrenia) were assigned to treatment with either an FGA (one of 11) or an SGA (one of 4), and qualit assessed after 12 months of treatment. No difference in quality of life or any other outcome measure was noted between patients assigned to the two groups. Results of these t to indicate that there are no differences in effectiveness between classic and atypical antipsychotics. Although a variety of methodological issues have been discussed with refe studies, one key attribute that should be noted is the fact that study inclusion/exclusion criteria and logistics led to patients in both studies being at low risk for EPS. Baseline EP patients in both studies were low. It was in the context of this study sample that the two studies did not discern any advantage for SGAs over FGAs. Given that the essential dist SGAs and FGAs is based on the lower liability of atypical antipsychotics to cause EPS (Figure 27–3), the two studies had low assay sensitivity in regard to this difference; in fact, detected any difference in EPS rates or anticholinergic use between classic and atypical antipsychotics.

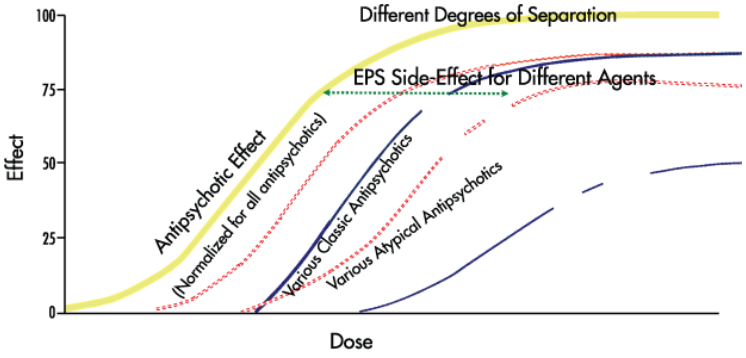

FIGURE 27–3. Clinical benefits of low extrapyramidal side effect (EPS) risk.

What CATIE and CUtLASS tell us is that avoiding EPS and anticholinergic use during effective antipsychotic therapy may explain the broader spectrum of efficacy sometimes obs versus classic antipsychotic agents. The lower risk of tardive dyskinesia observed with SGAs also appears to be driven by these agents' greater ability to achieve an equivalent a without EPS. The principal advantage of SGAs over FGAs thus appears to be the greater ease of the former in providing an adequate antipsychotic effect without causing EPS or anticholinergic to treat or prevent EPS. In patients at high risk for developing EPS, this difference is magnified, whereas in patients at low risk for developing EPS, this differenc substantial proportion of patients, however, this difference will likely be meaningful, and an antipsychotic effect without EPS can be achieved with less difficulty (because of the Figure 27–4) with an SGA rather than an FGA. It is true that previous industry-sponsored studies magnified the SGA–FGA difference by utilizing high doses of the high-potency as the FGA comparator and that this difference is smaller when more temperate doses of lower-potency FGAs are utilized. It is equally true that these differences were minimize CUtLASS by sample characteristics of low risk of EPS. The findings from CATIE and CUtLASS confirm broadly held clinical impressions that different agents are associated with di effects, which can make it challenging to achieve maximum efficacy while also maximizing safety and tolerability. However, it is these very differences among the antipsychotic heterogeneity in individual response and vulnerabilities, that may allow optimization of antipsychotic treatment. Different agents at different doses may provide the best balanc patients.

Substance-Induced Psychosis

As noted previously, conventional agents can reverse the psychosis associated with acute and chronic amphetamine intoxication as well as that associated with cocaine use. Ho acute dystonia must be considered in these populations, as dopamine receptor down-regulation is common, resulting in greater sensitivity to rapid D_2 blockade. Results in treat secondary to drugs acting in nondopaminergic mechanisms (such as hallucinogens) are less satisfactory, although there may be some role for the classic antipsychotics in treati (PCP) psychosis.

Personality Disorders

Although any personality disorder can be associated with transient psychotic features emerging under stressful conditions, Cluster B disorders are most often associated with th Treatment for the transient psychotic episodes has included short-term use of a high-potency antipsychotic. Although many symptoms of personality disorders may be amenabl pharmacological treatment, long-term conventional antipsychotic treatment has not been recommended, since core personality structure is largely resistant to pharmacological is a risk of tardive dyskinesia with long-term conventional antipsychotic therapy.

Affective Disorders

The utility of antipsychotic agents in the treatment of affective disorders with psychotic features is well known. However, their utility in the treatment of nonpsychotic depressio well. When profoundly negative views of oneself, the world, and the future become severe, the boundaries between psychotic and nonpsychotic depression can become blurred conventional antipsychotics (such as thioridazine) are FDA approved for the treatment of depression and anxiety without overt psychosis. However, they are rarely used for this because of the availability of other, more effective, and better-tolerated agents. The utility of conventional agents as adjuncts to mood stabilizers in the treatment of patients wi disorders has been well described, both in the acute management of mania and in the maintenance of severe and psychotic bipolar disorder. However, the newer atypical antips largely replaced conventional antipsychotics in the management of bipolar disorder.

Tourette's Syndrome

The tics present within Tourette's syndrome are believed to be due to a hyperdopaminergic state that is amenable to treatment by dopamine receptor antagonists. Pimozide is th antipsychotic with this indication, which is its only FDA-approved indication.

Huntington's Disease

Although there is no cure for Huntington's disease, the psychosis and choreiform movements associated with this disease may be ameliorated by dopamine receptor antagonism conventional antipsychotics carry FDA indications for treatment of this disease.

Nausea, Emesis, and Hiccups

The lower-potency antipsychotics exert a potent antiemetic effect through histamine$_1$ (H_1) receptor antagonism. This effect is closely related to their original role in reducing pe and emesis. Many well-known antiemetics, such as promethazine (Phenergan), are phenothiazines with a short-chain substitution. In addition, chlorpromazine is approved as o or intravenous therapy of intractable hiccups, depending on severity.

SIDE EFFECTS AND TOXICOLOGY

As noted earlier, it is the side-effect profile that serves to differentiate the conventional antipsychotics from one another rather than their efficacy in treating psychosis. They se at four major neurotransmitter receptor systems in the CNS: the dopamine type 2 receptor family (D_2, D_3, and D_4), muscarinic cholinergic receptors (M_1), α-adrenergic receptor histamine receptors (H_1) (Table 27–3).

Their therapeutic response in ameliorating the positive symptoms of schizophrenia is believed to be due to D_2 blockade in the mesolimbic dopamine tract (Table 27–4). Blockade the mesocortical, nigrostriatal, and tuberoinfundibular systems leads to the tract-related side effects described earlier in this chapter (see section "Mechanism of Action"). Lowe such as chlorpromazine, require higher doses to achieve therapeutic efficacy and therefore have a greater effect on other receptor systems. They have more antihistaminergic, a antiadrenergic actions. However, they have fewer D_2-related side effects because of their lower affinity to D_2 receptors and relatively high anticholinergic activity. Higher-poten haloperidol, produce more D_2-related movement disorders and prolactin elevation but otherwise have a cleaner side-effect profile, having fewer anticholinergic, antiadrenergic, antihistaminergic side effects. Anticholinergic action often leads to dry mouth (xerostomia), blurred vision (mydriasis), constipation, urinary retention, sinus tachycardia, prolor confusion, impaired cognition, paralytic ileus exacerbation of open-angle glaucoma, and drowsiness. Antagonism of α1-adrenergic receptors is associated with orthostatic hypot prolongation, reflex tachycardia, dizziness, incontinence, and sedation. Antagonism of α_2 receptors can be associated with retrograde ejaculation and priapism. Antagonism of H to sedation, drowsiness, and weight gain. The frequencies of adverse reactions of classic antipsychotic agents are summarized in Table 27–5.

Cognitive Side Effects

CNS side effects of conventional antipsychotics can be subclassified into cognitive and neuromuscular side effects. Cognitive effects include sedation, confusion, disturbed conc impairment, and delirium. Antihistaminergic and anticholinergic actions lead to the sedation and slowed mentation. These effects, which are most pronounced in the lower-pote chlorpromazine), are most severe earlier in treatment, with some tolerance developing over time. Anticholinergic delirium is the most common cause of medication-induced deli results in high rates of morbidity and mortality (over 20% mortality), this potential side effect is important, especially in populations of individuals who are more sensitive to an medications, such as the elderly. In addition, every antipsychotic—especially the low-potency drugs—can potentially lower the seizure threshold.

Extrapyramidal Side Effects

Neuromuscular CNS side effects are due to antagonism of D_2 receptors in the nigrostriatal dopaminergic pathway. Generally, antipsychotics manifest EPS when dopaminergic bl 75%–80% of D_2 receptors. EPS effects are most frequent with the high-potency agents such as haloperidol.

Acute-Onset EPS

Acute-onset EPS include medication-induced parkinsonism, acute dystonia, and akathisia. ***Antipsychotic-induced parkinsonism*** occurs in 15% of patients after several weeks of more common in patients older than 40 years, although it can occur at any age. Symptoms are identical to those of Parkinson's disease and include muscle stiffness (lead-pipe r rigidity, shuffling gait, stooped posture, drooling, bradykinesia, resting tremor, masked facies, and akinesia. Slowed, restricted movements of the body and face may be mistake being due to depression or the negative symptoms of schizophrenia. It is estimated that up to 10% of patients may experience an acute dystonic episode, which usually occurs hours or days of treatment. It is more common in men younger than 30 years and women younger than 25 years, in recent cocaine users, and when intramuscular doses of high antipsychotics are used.

Dystonia is an acute sustained, painful muscular contraction that may manifest as either generalized or focal in effect on the musculature. Potential areas of involvement include (protrusions, twisting), jaw, neck (spasmodic retrocollis or torticollis), and back (opisthotonos). If the dystonia involves the eyes, it results in a symmetrical or unilateral upwar called an ***oculogyric crisis***. Unlike previously mentioned dystonias, an oculogyric crisis can also occur late in treatment with antipsychotics. A laryngeal dystonia can result in suc secondary to a patient's inability to breathe. Resurgent dopamine activity in the basal ganglia that occurs when the CNS level of the antipsychotic begins to decrease is thought t mechanism of action. Dystonia can be extremely uncomfortable and frightening for patients and can lead to noncompliance with medication for fear of recurrence. Treatment of rapid diagnosis and intravenous administration of antihistaminergic or anticholinergic agents. Anticholinergic agents are often initiated with high-potency antipsychotics in an e side effect, but long-term use may increase the risk of developing tardive dyskinesia.

Akathisia is a subjective feeling of motor restlessness in which patients feel an irresistible urge to move continuously. It is described as an unpleasant sensation and may result Akathisia can occur at any time during treatment and is the most prevalent EPS. It frequently leads to noncompliance with medications and is believed to increase suicide risk in

Late-Onset EPS

Tardive dyskinesia is characterized by a persistent syndrome of involuntary choreoathetoid movements of the head, limbs, and trunk. It generally takes at least 3–6 months of e antipsychotics before the disorder develops. Perioral movements involving buccolingual masticatory musculature are the most common early manifestation of tardive dyskinesia

Tardive dyskinesia has an estimated yearly incidence of 5% among adults and as high as 25% in the elderly who receive continuous conventional antipsychotic therapy and has source of litigation in past psychiatric practice. The risk of developing tardive dyskinesia is reported to increase with age and to be higher in certain ethnic groups; female gende mood disorders, and early onset of EPS have also been associated with increased risk of tardive dyskinesia.

Tardive dyskinesia may be masked by continuing dopamine blockade and has a variable course following development. Over time, spontaneous resolution or improvement has b some individuals. There is no single effective treatment, although treatment with clozapine has been reported to improve symptoms. Tardive dyskinesia is thought to be seconda of postsynaptic dopamine receptors in the basal ganglia secondary to long-term dopamine blockade. Cases of tardive dyskinesia have been described with every antipsychotic, a high-potency conventional agents are the most closely related causative agents. Other tardive syndromes include tardive dystonia, tardive akathisia, and tardive pain.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) is a poorly understood syndrome that usually occurs within hours or days of initiation of antipsychotic treatment. This syndrome is chara muscular rigidity, hyperpyrexia (101–107°F), autonomic instability (hypo- or hypertension, tachycardia, diaphoresis, pallor), and altered consciousness. NMS has an estimated 0.02%–2% and carries a mortality rate of 20%–30%. Death often occurs secondary to dysrhythmias, renal failure secondary to rhabdomyolysis, aspiration pneumonia, or respi Laboratory findings include elevated creatine phosphokinase (CPK), elevated white blood cell count, elevated liver enzymes, myoglobinemia, and myoglobinuria. The syndrome 10–14 days.

Treatment requires immediate discontinuation of the offending antipsychotic and supportive care with aggressive intravenous hydration. In the past, mild cases of NMS were tre intravenous bromocriptine, while more severe cases were treated with intravenous dantrolene. However, evidence-based studies of NMS treatment have never been performed infrequent occurrence.

NMS is more common in men than in women and occurs more often within the summer months. Risk factors include dehydration, poor nutrition, presence of mood disorders or o syndromes, rapid titration, use of physical restraints, and intramuscular usage. Although onset of NMS is possible at any point during treatment, a significant proportion of the c manifest during the first 2 weeks of antipsychotic treatment.

Cardiac Effects

α-Adrenergic antagonism is associated with orthostatic hypotension with reflex tachycardia, with tolerance possibly developing later in the treatment course. Orthostasis is imp an increase in falls and related injuries. Serious hypotension should never be treated with epinephrine, since this hypotension is mediated through intense α receptor blockade a dilation. Administration of epinephrine may only exacerbate this problem by causing further vascular dilation through its β receptor stimulation. If necessary, agents such as no be used, as this type of agent will stimulate only α-adrenergic receptors, reversing vasodilation.

Recent studies involving several conventional antipsychotics have drawn attention to the risk of cardiac dysrhythmias, which is especially prominent with use of lower-potency antipsychotics. High dosage, rapid titration, intramuscular administration, and especially intravenous administration may be associated with a lengthening of the QRS or QTc int resulting risk of serious dysrhythmias such as torsades de pointes and ventricular fibrillation. Recent studies involving thioridazine have raised concerns about piperidine antips led to a decrease in their use, despite an infrequent incidence of fatal dysrhythmias in clinical practice. In reality, torsades de pointes is rarely encountered during treatment wi antipsychotics, although some speculate that a syndrome of unexplained sudden death described with all conventional antipsychotics may be related to sudden dysrhythmias.

Gastrointestinal Side Effects

As expected, the anticholinergic actions of conventional agents include dry mouth, nausea, vomiting, and constipation that can progress to paralytic ileus. Antihistaminergic acti with medication-related weight gain, which greatly increases the patient's risk of developing diabetes.

Cholestatic jaundice is a hypersensitivity reaction described with the aliphatic phenothiazines, especially chlorpromazine (incidence of 0.1%). This reaction typically manifests months of treatment and presents with nausea, malaise, fever, pruritus, abdominal pain, and jaundice, with resulting elevations in levels of bilirubin and alkaline phosphatase. lasts more than 2–4 weeks after discontinuation.

Weight Gain, Diabetes Mellitus, and Dyslipidemia

With the introduction of atypical antipsychotics, several of which cause significant weight gain, there is renewed awareness of the metabolic side effects associated with antips such as obesity, elevated cholesterol and triglyceride levels, and an increased risk of diabetes mellitus. These metabolic changes increase the risk of ischemic heart disease and increased mortality observed in schizophrenia. Antihistaminergic action is associated with medication-related weight gain, which greatly increases the patient's risk of developi Diabetes is currently described as a worldwide epidemic. Serotonin 5-HT_{2C} receptor blockade also significantly contributes to weight gain; anticholinergic and 5-HT_{2A} antagonis contribute. There are significant differences among FGAs with reference to their propensity to cause these metabolic adverse effects. Molindone is the least likely to cause weig thioridazine and chlorpromazine are among the most likely to do so. In general, high-potency agents cause less weight gain and related metabolic adverse effects than low-pote

Genitourinary Side Effects

Renal effects secondary to blockade of M_1 receptors include urinary hesitancy or retention that can lead to a comparable increase in urinary tract infections in both genders. As previously, antagonism of tuberoinfundibular dopaminergic tracts increases prolactin secretion. Hyperprolactinemia causes both endocrine and sexual side effects, including gy galactorrhea, diminished libido, erectile dysfunction, amenorrhea, decreased bone density, menstrual irregularities, infertility, delayed ovulation, anorgasmia, and possibly incr cancer.

Sexual difficulties, including erectile dysfunction, retrograde ejaculation (due to blockade of α_2-adrenergic receptors), anorgasmia, and occasionally priapism, can also occur.

Hematological Side Effects

Hematological effects of conventional antipsychotics include transient leukopenia (white blood cell [WBC] count <3,500/mm^3), which is common but not usually problematic, a (WBC count <500/mm^3), a life-threatening problem. Agranulocytosis occurs most often during the first 3 months of treatment, with an incidence of 1 in 500,000. It is more com women older than 40 years. The mortality rate related to this agranulocytosis may be as high as 30%. Aliphatic and piperidine phenothiazines are the most common causal agen conventional antipsychotics. Rarely, thrombocytopenic or nonthrombocytopenic purpura, hemolytic anemia, and pancytopenia may occur.

Ocular Side Effects

In addition to direct anticholinergic effects such as blurred vision (mydriasis and cycloplegia) and exacerbation of open-angle glaucoma, direct optic toxicity has been described antipsychotics are associated with several kinds of optical pathology, including pathology of the lens, cornea, and retina.

Lenticular opacities have been reported with some phenothiazines, including perphenazine, chlorpromazine, and thioridazine. An irreversible increase in retinal pigmentation ha with thioridazine when high dosages are used (>800 mg/day). This retinal pigmentation, which can progress even after drug discontinuation, can lead to reduced visual acuity Early symptoms include poor night vision and secondary nocturnal confusion. Two reports of ocular pathology in young schizophrenic inpatients and outpatients who were treat with the older antipsychotics demonstrated a high rate of overall ocular pathology (82%) and a much higher rate of lenticular opacities (22%–26%) than the general populatio decade of life (0.2%). The high rate of lenticular opacities in patients with schizophrenia is striking and may be due in part to antipsychotic treatment but is also related to othe factors, such as diabetes, smoking, exposure to ultraviolet radiation, stress, and facial trauma.

Dermatological Side Effects

Cutaneous side effects of conventional antipsychotics involve hypersensitivity rashes—most commonly maculopapular erythematous rashes of the trunk, face, neck, and extrem photosensitivity reactions that can lead to severe sunburn. Care must be taken with injectable versions of many antipsychotics because of direct dermatological toxicity if the sk layers are exposed. Prolonged use of chlorpromazine can lead to blue-gray discoloration in body areas exposed to sunlight.

Adverse Effects in Special Populations

In general, there have been few controlled studies of conventional antipsychotics within the pediatric population and almost none during pregnancy and the peripartum period. availability of atypical antipsychotics, most of the conventional agents have fallen into disuse in pediatric populations. The only conventional antipsychotic agent FDA approved f childhood is pimozide, for the indication of Tourette's syndrome.

It is ethically problematic to design controlled studies involving pediatric populations and women during pregnancy because of the long-term and serious side effects associated agents. However, safety concerns in the peripartum mother sometimes require the use of antipsychotics to ameliorate psychosis (whether it was preexisting or developed perip and extremes of affective syndromes. Potential threats of the drugs to the mother, fetus, and/or children must be carefully weighed against the potentially life-threatening natu psychiatric pathology. Although no formal drug trials have been performed, haloperidol has been the most widely used antipsychotic in the peripartum period, with the best emp of safety during that time. However, one must be mindful that haloperidol has been shown to cross the placenta and to be present within breast milk. Also, animal models have complications such as decreased gestational size and infant withdrawal syndromes. Chlorpromazine should not be used during pregnancy, due to a relatively worse empirical si including gray baby syndrome. Use of antipsychotics during pregnancy should be undertaken only with careful consideration of the risks, benefits, and alternatives with the obs who is managing the remainder of the patient's prenatal care.

Geriatric populations pose a special challenge because of the increased sensitivity to all side effects of antipsychotics, impaired hepatic and renal metabolism of these agents, in delirium, increased use of other medications, and increased risk of tardive dyskinesia. Annual incidence of tardive dyskinesia in the elderly seems to increase exponentially with estimated to be as high as 10-fold greater than the incidence in younger patients. Increasing permeability of the blood–brain barrier with age and an increase in adverse side ef necessitate much lower dosing of conventional antipsychotics, as well as routine consideration of taper and discontinuation of these agents. Alternative means of managing elde as other medical, behavioral, and environmental means of management, should be sought on a continuing basis. If antipsychotic therapy is still required, cautious utilization an monitoring are essential.

Summary of Side Effects

The antagonistic action of the conventional antipsychotics on D_2 receptors in the nigrostriatal, mesocortical, and tuberoinfundibular tracts, as well as blockade of adrenergic, his muscarinic cholinergic receptors, produces many undesirable side effects involving multiple body systems. The lower-potency agents cause more peripheral side effects and les tract–related pathology, while the reverse is true of the higher-potency agents.

DRUG–DRUG INTERACTIONS

Careful consideration of a patient's existing drug regimen should be given prior to the initiation of antipsychotic therapy. Except under very special circumstances, antipsychotic monotherapy, after selection of the appropriate agent. Clear rationales should be provided, and target symptoms should be identified and monitored routinely. Oral forms of med used whenever possible, and the patient's medical condition should be routinely monitored and patients should have physical exams regularly.

Protein Binding

Since conventional antipsychotics are tightly protein bound, care must be taken when these medications are administered with other highly protein-bound medications. Mutual c medications such as phenytoin, digoxin, warfarin, and valproate could lead to a short-term increase in serum levels of these drugs and of the conventional antipsychotic, with a to subtherapeutic levels through increased elimination.

Cytochrome P450 Inhibition

As mentioned previously, conventional antipsychotics are primarily hepatically metabolized through the cytochrome P450 2D6 and 3A4 enzymes. In addition, each inhibits the 2 degree. Care must be taken when these agents are coadministered with such potent 2D6 inhibitors as fluoxetine, paroxetine, cimetidine, erythromycin, and certain class IC anti as quinidine. Similarly, potent 3A4 inhibitors, such as nefazodone, fluoxetine, fluvoxamine, and ketoconazole, should be used with care. Inhibitors of 2D6 and 3A4, as well as co substrates, should be used carefully with conventional antipsychotics because of their potential to increase plasma levels and subsequent side effects. Also, consideration shoul other drugs that are primarily metabolized by 2D6 are coadministered with conventional agents, because of their potential to increase serum levels of these drugs, including tric antidepressants, selective serotonin reuptake inhibitors, some antiarrhythmics, and several β-blockers. CYP1A2, induced by nicotine and inhibited by estrogen, plays a role in m antipsychotics. The complexity of these and other potential drug interactions requires a psychiatrist who is familiar with general medicine if these medicines are to be used com Needless patient suffering and lawsuits are the only alternative.

Other Interactions

A syndrome of neurotoxic encephalopathy has been described on coadministration of lithium with haloperidol or thioridazine. Care should be taken if these agents are coadminis individuals older than 50 years.

CONCLUSION

Despite the presence of some serious side effects, the conventional antipsychotics revolutionized the practice of psychiatry and the treatment of the severely mentally ill throug They remain effective agents despite their burdensome side-effect profiles. However, as time progresses, newer atypical antipsychotics appear to have eclipsed these agents to newer short-acting intramuscular and depot formulations have been introduced. It is estimated that less than 10% of current antipsychotic prescriptions in the United States ar agents. The recognition of weight gain and related metabolic adverse effects in conjunction with atypical antipsychotic therapy, along with the results of CATIE and CUtLASS ind difference in effectiveness between classic and atypical agents, has reinvigorated interest in conventional agents. As the metabolic profiles of both classic and atypical agents a elucidated, it is conceivable that there may be a resurgence in the use of classic agents if they are found to provide a more benign metabolic profile than atypical agents. Motor s narrower antipsychotic–EPS dose window will continue to be limiting factors.

As models of psychosis and antipsychotics are further refined, additional neurotransmitter systems will be addressed in the pathology of schizophrenia and psychosis. Unfortun attempts to treat schizophrenia and reduce side effects by blocking a single neurotransmitter system were unsuccessful. The next generation of drugs following atypical antipsy address glutamatergic and cholinergic systems to target cognitive deficits and certain neurophysiological aberrations, such as poor prepulse inhibition. Clearly, much work rema of psychopathology of the human mind is unraveled. Conventional antipsychotics will always be remembered for their vital role as the foundation of antipsychotic pharmacother impetus for the remarkable neuropharmacological progress in psychiatric neuroscience over the second half of the twentieth century. They retain an important, if limited, role in armamentarium in the first decade of the twenty-first century.

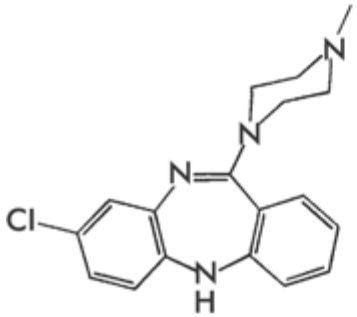
Chapter 28. Clozapine

HISTORY AND DISCOVERY

Clozapine has played a critical role in the history of therapeutics for psychosis. When clozapine was initially developed in the 1960s (following its synthesis in 1958 in Switzerland), there was skepticism as to whether an agent that barely caused catalepsy in rodents could be an effective antipsychotic. According to Hippius (1999), there was limited enthusiasm for this drug because it was inconsistent with the "neuroleptic dogma" that extrapyramidal side effects (EPS) were an essential feature of an antipsychotic agent. Nevertheless, Hippius and others challenged this dogma and supported clozapine's development in Germany. As a result, clozapine was eventually marketed in a number of countries in Europe.

Enthusiasm about clozapine's unique profile turned to despair when it was reported that 13 patients in Finland developed agranulocytosis during treatment with clozapine and that 8 of these patients died (Griffith and Saamerli 1975). This led to a near-halt in research on clozapine and attempts to switch patients to other agents. However, some individuals demonstrated substantial deterioration when they were switched (Hippius 1999). These patients were changed back to clozapine and carefully monitored with regular white blood cell (WBC) counts. It was subsequently confirmed that clozapine-induced agranulocytosis was reversible. If clozapine was discontinued before patients developed infections, the drug could be readministered safely (Honigfeld et al. 1998). Moreover, studies revealed that clozapine was particularly effective for patients who were severely ill and for patients who had failed to respond to treatment with conventional antipsychotics.

These observations led to attempts to gain approval for clozapine in the United States for patients who failed to respond to other antipsychotics. This resulted in a multicenter study (Kane et al. 1988; described in greater detail later in this chapter) in which severely ill inpatients with a history of poor responsiveness to at least three antipsychotics were assigned to a 6-week comparison of either clozapine or chlorpromazine with benztropine. Clozapine was significantly more effective on a broad range of psychopathology that included both positive and negative symptoms. This breadth of improvement suggested not only that clozapine was more effective than chlorpromazine but also that it was qualitatively different. Another study (Claghorn et al. 1987) evaluated the effectiveness of clozapine and chlorpromazine in patients with either tardive dyskinesia or EPS. This report also found that clozapine was superior in a broad range of psychopathology. The completion of these studies was instrumental in the approval of clozapine by the U.S. Food and Drug Administration (FDA) in 1990. Approval in the United States was followed by its introduction in a number of other countries.



The discovery that clozapine was an effective antipsychotic with minimal EPS led to a reassessment of models for developing antipsychotic agents. This reassessment, in turn, led to the later development of a new generation of antipsychotics. Moreover, attempts to understand clozapine's mechanism of action have had important effects on current views of the pharmacology of schizophrenia.

STRUCTURE–ACTIVITY RELATIONS

Clozapine belongs to the group of tricyclic antipsychotics known as the dibenzepines. This group is characterized by a seven-member central ring (Figure 28–1). The antipsychotic dibenzepines include

a loxapine-like group of compounds (the dibenzoxazepines) and a clozapine-like group (the dibenzodiazepines). Substitutions in the clozapine group resulted in the development of both quetiapine and olanzapine.

PHARMACOLOGICAL PROFILE

Animal behavioral models have been of limited use in schizophrenia. The primary problem is that there is not a well-accepted animal model for psychopathology in schizophrenia. A number of models—including latent inhibition of the conditioned response, prepulse inhibition, and P_{50} gating—are being studied, and these models suggest unique properties of clozapine that may be clinically relevant. The models used in the development of antipsychotics over the years were empirical models based on dopamine blockade. Criteria for antipsychotic action included the ability of the agent to cause catalepsy at higher doses as well as its antagonism of stereotypies in animals resulting from the administration of amphetamine. Although clozapine meets neither of these criteria, it does block the conditioned avoidance response, suggesting that it has antipsychotic activity.

One model of schizophrenia is based on the theory that individuals with the disorder are impaired in their ability to filter out irrelevant internal or external stimuli. Clinically, patients may describe the experience of being inundated by an excess of stimulation. One method of studying impairments of gating employs a paradigm known as prepulse inhibition (PPI) of the startle reflex. PPI uses a stimulus, such as a puff of air aimed at the eye, that evokes a startle response. The prepulse is a weak stimulus that is presented just prior to the stimulus that elicits a startle. The insertion of the prepulse inhibits the startle response. The usefulness of this model is supported by the observation that in comparison with healthy control subjects, patients with schizophrenia (as well as those with other psychiatric illnesses) demonstrate decreased PPI. Moreover, these PPI deficits correlate with the severity of thought disorder and psychotic symptoms (Braff et al. 1999).

The PPI model can be used in both rodents and humans. Moreover, as a model of gating disturbances, it has face validity. In rodents, dopamine receptor agonists, serotonin$_2$ (5-HT$_2$) receptor agonists, *N*-methyl-D-aspartate (NMDA) receptor antagonists, and isolation rearing can result in impairment of PPI (Geyer et al. 2001). Clozapine—as well as other antipsychotics—restores PPI in rats treated with apomorphine (Swerdlow and Geyer 1993) as well as rats treated with the NMDA antagonist ketamine (Swerdlow et al. 1998). In addition, clozapine restores PPI in rats exposed to social isolation (Varty and Higgins 1995). In patients with schizophrenia, clozapine was superior to typical antipsychotics in normalizing PPI (Kumari et al. 1999).

PHARMACOKINETICS AND DISPOSITION

Peak plasma levels of clozapine are reached approximately 2 hours after oral administration. The elimination half-life is about 12 hours. Patients will usually reach steady-state plasma concentrations

in less than 1 week. The coadministration of highly protein-bound drugs may lead to increased free clozapine levels, although the total (free plus bound) levels may be unchanged. Clozapine's volume of distribution is lower than that of other antipsychotic drugs but is nonetheless large, with a mean of 2.0–5.1 L/kg (range: 1.0–10.2 L/kg).

Clozapine undergoes extensive first-pass metabolism in the liver and gut. Although clozapine is predominately metabolized by cytochrome P450 (CYP) 1A2, CYP2D6 and CYP3A3 also contribute (Buur-Rasmussen and Brosen 1999).

Plasma concentrations of clozapine average about 10–80 ng/mL per mg of drug given per kg of weight. Thus, a typical daily dose of 300–400 mg (about 5 mg/kg) is associated with levels ranging between 200 and 400 ng/mL. However, there is considerable variability among patients treated with clozapine. This was demonstrated by Potkin et al. (1994), who administered 400 mg of clozapine to a group of patients and found a 45-fold variation in plasma concentrations. A number of studies focused on the clinical implications of this variation in plasma concentrations. These studies, when taken together, indicate that patients are more likely to do well when their levels are greater than 350 ng/mL (Bell et al. 1998; Kronig et al. 1995; D. D. Miller 1996; D. D. Miller et al. 1994; Potkin et al. 1994). If patients have not responded after 6 weeks with a plasma level of 250 ng/mL, the clinician should increase the level to approximately 350 ng/mL. High levels, such as 600 ng/mL, are not associated with a greater likelihood of improvement than are moderate levels, and they may be associated with a higher incidence of side effects. Therefore, patients with high levels and side effects may benefit from having the dosage reduced. In interpreting plasma concentrations of clozapine, it is important for clinicians to consider if the laboratory is reporting just the parent drug or clozapine plus norclozapine. If it is the combination, levels will be higher.

MECHANISM OF ACTION

The explanation for clozapine's unique effectiveness remains controversial. As mentioned earlier, clozapine was the first agent to challenge the dogma that antipsychotic efficacy required high levels of EPS. There are a number of characteristics of clozapine that could explain how it can reduce psychosis without causing EPS.

Clozapine's low incidence of EPS could be explained by its low dopamine$_2$ (D_2) receptor occupancy at therapeutic doses. Studies using positron emission tomography (PET) with selective D_2 receptor ligands, such as raclopride, make it possible to determine the proportion of D_2 receptors that are occupied by an antipsychotic in a particular individual at a particular time. These studies found that conventional antipsychotics are effective when approximately 80% of receptors are occupied (Farde et al. 1992). Higher levels of occupancy may increase EPS, but they do not result in greater efficacy. In contrast, clozapine is effective when it occupies 20%–67% of D_2 receptors. This observation may explain two important properties of clozapine: its tendency to cause very little EPS and the suggestion that its effectiveness is associated with something more than just D_2 receptor occupancy.

It has also been suggested that clozapine's properties are associated with its combination of relatively low affinity for D_2 receptors and high affinity for other receptors, including 5-HT_{2A}, 5-HT_{1C}, adrenergic, and cholinergic receptors. Most of the attention has focused on clozapine's high ratio of 5-HT_{2A} to D_2 receptors, because this property is shared by nearly all of the other second-generation antipsychotics (SGAs). Moreover, serotonin can modulate dopamine neurons in the substantia nigra, which in turn may decrease EPS. Clozapine also has a very high affinity for the dopamine$_4$ (D_4) receptor. The D_4 receptor is widely distributed in the cortex and less so in striatal areas. However, other agents with high D_4 receptor activity have failed to demonstrate antipsychotic activity.

Another theory—supported by both Seeman (2002) and Kapur and Seeman (2001)—hypothesizes that the lack of EPS with clozapine and other SGAs is related to their fast dissociation from the D_2 receptor. Conventional antipsychotics tend to bind more tightly to dopamine receptors than to dopamine itself.

Nearly all of the SGAs, including clozapine, bind more loosely and tend to come off the receptor more readily in the presence of dopamine. As a result, these newer agents may block these receptors more transiently, coming off the receptor to permit more normal dopamine transmission. Another approach to understanding the mechanism of action of clozapine is based on the finding that acute administration of conventional antipsychotic drugs to rodents leads to an increase in the firing of dopamine neurons in the substantia nigra and the ventral tegmental area. However, after 3 weeks of treatment with these agents, there is a decrease in the number of firing dopamine neurons in both of these areas. This prolonged decrease in firing has been referred to as *depolarization inactivation.* Inactivation in the ventral tegmental area has been used to explain the sustained therapeutic effectiveness of these agents, and inactivation in the substantia nigra has been used to explain EPS. Clozapine—along with other SGAs—causes inactivation in the ventral tegmental area, but not in the substantia nigra (Chiodo and Bunney 1983), suggesting that these agents have different effects in these two brain areas.

INDICATIONS AND EFFICACY

Acute Schizophrenia and Schizoaffective Disorder

Because of its side-effect profile, clozapine is the only available antipsychotic that should not be administered as a first-line agent for schizophrenia or schizoaffective disorder. However, this does not mean that clozapine is ineffective in these disorders. Early trials comparing clozapine with haloperidol and chlorpromazine indicated that clozapine was at least as effective as the other agents for acutely psychotic patients. In the chlorpromazine comparison (Fischer-Cornelssen and Ferner 1976), the advantages were most apparent for the more severely ill patients. The comparison with haloperidol (Honigfeld et al. 1984) was carried out in a more severely ill group of patients and found a substantial advantage for clozapine. A report by Shopsin et al. (1979) compared clozapine, chlorpromazine, and placebo in 31 newly admitted patients with acute illness. Clozapine was found to be superior to both chlorpromazine and placebo. Taken together, these early studies indicate that clozapine is effective for treatment of a broad range of individuals with acute psychosis. In China, for example, clozapine is commonly prescribed as a first-line antipsychotic for acute schizophrenia.

Treatment-Refractory Schizophrenia

As noted above, early studies suggested that clozapine was particularly effective in patients with more severe treatment-refractory forms of schizophrenia. This was important when it was discovered that clozapine was associated with a risk of agranulocytosis. Given that clozapine was viewed as an agent that might be helpful for patients who had failed to respond to other antipsychotics, a study was designed to test whether there was a role for clozapine in this population. The result was the design of a multicenter study comparing clozapine with chlorpromazine in severely ill patients with treatment-refractory schizophrenia (Kane et al. 1988). Treatment-refractory illness was characterized on the basis of a history of drug nonresponsiveness and a failure to improve during a 6-week trial of up to 60 mg of haloperidol. Clozapine resulted in greater improvement in nearly every dimension of psychopathology. Clozapine-treated patients were less depressed and less anxious. In addition, they demonstrated substantial improvements in Brief Psychiatric Rating Scale (BPRS) items that measured emotional withdrawal, motor retardation, and blunted affect. These items may reflect the negative symptoms of schizophrenia and suggest that clozapine is more effective than conventional antipsychotics in treating negative symptoms. Thirty percent of the clozapine-treated patients met stringent improvement criteria, compared with only 4% of those treated with chlorpromazine. However, this study was only 6 weeks in duration and may have underestimated the proportion of patients who improved with clozapine treatment.

Other studies suggest that the proportion of patients improving with clozapine treatment will be higher if clozapine is continued for a longer time. For example, a 16-week trial by Pickar et al. (1992)

found a 38% improvement rate. A more recent report (Kane et al. 2001) found that 60% of patients with treatment-refractory illness improved after a 29-week trial on clozapine.

The early studies of clozapine focused on individuals who had been unresponsive to first-generation antipsychotics (FGAs) and had subsequently been switched to clozapine. There are a number of reasons to suspect that the proportions of patients responding to clozapine are lower if patients had previously been treated with other SGAs. First, failure to respond to an FGA may result from an inability to tolerate an adequate dose because of EPS. In addition, a number of studies suggest that patients who fail to respond to FGAs may improve if they are changed to an SGA other than clozapine. However, comparisons of clozapine and SGAs have yielded results that can be difficult to interpret. For example, some studies comparing risperidone (Bondolfi et al. 1998) or olanzapine (Bitter et al. 2004; Tollefson et al. 2001) with clozapine in patients with treatment-refractory illness suggested that these agents had similar efficacy. Other studies (Azorin et al. 2001; Breier et al. 1999) suggested advantages for clozapine. Volavka et al. (2002) compared clozapine, risperidone, olanzapine, and haloperidol in patients with suboptimal responses to FGAs. The study showed advantages for the SGAs over haloperidol on total Positive and Negative Syndrome Scale (PANSS) scores. Effect sizes for improvement were largest for olanzapine and clozapine, smallest for haloperidol, and intermediate for risperidone. Clozapine was more effective than the other medications for negative symptoms.

Two large trials compared clozapine with SGAs in patients with treatment-resistant illness. In the United States, the National Institute of Mental Health (NIMH) Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) compared clozapine with risperidone, olanzapine, or quetiapine in patients with schizophrenia who had failed to respond in an earlier phase of the study because of a lack of efficacy (Stroup et al. 2006). Clozapine was administered open label, whereas the other antipsychotics were administered double-blind. Patients assigned to clozapine had the lowest discontinuation rates, with 56% of patients on clozapine discontinuing treatment, compared with 71% on olanzapine, 86% on risperidone, and 93% on quetiapine. Clozapine-treated patients also showed greater symptom improvements than those receiving the other agents. Another trial in the UK, the Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study—band 2 (CUtLASS-2) (Lewis et al. 2006), randomly assigned 136 patients who had responded poorly to two prior antipsychotics to either clozapine or an SGA selected prior to the randomization. Patients who received clozapine demonstrated greater improvement than those on the comparison drugs.

Chakos et al. (2001) conducted a review and meta-analysis of studies comparing the efficacy and tolerability of clozapine with that of FGAs and other SGAs in treatment-resistant schizophrenia. Clozapine was superior to FGAs, but findings for other SGAs were inconclusive. (However, this study was carried out prior to CATIE and CUtLASS-2, both of which supported superior efficacy for clozapine.) Despite clozapine's advantages, a significant number of patients with treatment-refractory illness do not respond to clozapine. The Chakos et al. (2001) meta-analysis found that in most studies, fewer than half of the patients with treatment-resistant illness responded to clozapine. Additionally, many patients who do respond favorably to clozapine continue to have significant symptoms that impair their functioning in the community.

Taken together, these studies—particularly CATIE and CUtLASS-2—indicate that clozapine has an important role in the treatment of patients who have failed to respond to either FGAs or other SGAs. Clozapine's advantages are clearest in patients who have failed to respond to FGAs but are still apparent in those who have had an inadequate response to other SGAs. Because clozapine is associated with a risk of agranulocytosis and other side effects (summarized later in this chapter under "Side Effects and Toxicology"), patients should probably receive a trial of one or two other SGAs before receiving a trial of clozapine. Clinical guidelines (Lehman et al. 2004a, 2004b; Marder et al. 2002; A. L. Miller et al. 2004) differ to a minor degree on the number of trials that should precede a trial with clozapine, but most recommend at least two agents, one of which is an SGA. There is a

consensus that patients should not be considered to have treatment-refractory illness until they have received an adequate trial with clozapine.

Hostile and Aggressive Behavior in Schizophrenia

Clozapine may have other advantages for patients with schizophrenia. A number of studies suggest that clozapine may decrease hostility and aggression, compared with other agents. In a study of 157 inpatients (Citrome et al. 2001), clozapine resulted in greater reductions in the hostility item from the PANSS than did the FGAs and other SGAs. A study by Chengappa et al. (2003) found significant reductions in the rates of seclusion and restraint in schizophrenia patients who received clozapine during the first 3 years after its introduction. Other randomized trials have consistently found that patients treated with clozapine experience less hostility and fewer aggressive behaviors than patients on comparators (Essock et al. 2000; Kane et al. 1988). These findings suggest that clozapine may be of particular benefit to patients with treatment-refractory illness who demonstrate hostile and aggressive behaviors.

Schizophrenia Patients at High Risk for Suicide

Clozapine may also be a preferred agent for patients with schizophrenia who are at a higher risk for suicide. Large epidemiological studies have found that mortality from suicide is reduced among individuals taking clozapine (Reid et al. 1998; Walker et al. 1997). Meltzer and Okayli (1995) followed patients who were changed to clozapine and found a reduction in the number of serious suicide attempts as well as in expressed depression and hopelessness. The most convincing study was a comparison of clozapine and olanzapine in 980 patients with schizophrenia who were considered at risk for suicide. In that study, clozapine was more effective in reducing the risk of suicide (Meltzer 2002).

Clozapine may also have advantages for patients with polydipsia–hyponatremia syndrome (Canuso and Goldman 1999). These patients tend to intoxicate themselves through excessive water drinking. Hyponatremia may result in seizures.

Schizophrenia With Comorbid Substance Abuse

Although the effectiveness of clozapine in patients with comorbid substance abuse has not been demonstrated in randomized, controlled trials, there is some supporting evidence from naturalistic studies. One retrospective study (Green et al. 2003) found that patients treated with clozapine were more likely than those treated with risperidone to abstain from alcohol and cannabis use. A prospective study (Green et al. 2007) found that patients treated with clozapine were often able to reduce their substance abuse. This finding was supported by other prospective studies (Brunette et al. 2006; Drake et al. 2000), indicating that clozapine is effective for reducing substance abuse.

Supplemental Antipsychotic Treatment in Partial Responders to Clozapine

A number of studies have evaluated augmentation strategies for individuals who are partial responders to clozapine. Paton et al. (2007) reviewed open and randomized, controlled trials in which partial responders to clozapine received supplemental treatment with another antipsychotic. Among the controlled trials, three used risperidone as the supplementing agent and one used sulpiride. The two studies with a duration of greater than 10 weeks favored augmentation, whereas the briefer studies did not.

Maintenance Therapy in Schizophrenia

Clozapine use has largely been confined to patients with treatment-refractory schizophrenia. As a result, clozapine has not been studied in the traditional relapse prevention trial in which patients who are stable are randomly assigned to either clozapine or a comparator. Nevertheless, there are substantial data supporting the long-term effectiveness of clozapine. Breier et al. (2000) evaluated

the outcomes of 30 patients with schizophrenia who were treated with clozapine for 1 year. Patients taking clozapine experienced fewer relapses and rehospitalizations than they did in the year prior to being changed to clozapine. A study in the state hospitals in Connecticut compared patients who were assigned to clozapine with patients who were maintained on their usual antipsychotics (Essock et al. 2000). Although clozapine did not result in a greater likelihood of hospital discharge, patients who were treated with clozapine had a higher likelihood of remaining in the community following discharge. This finding supports the observation that clozapine is associated with a reduced risk of relapse, compared with a conventional antipsychotic.

A study from the U.S. Department of Veterans Affairs (VA) Cooperative Studies Program compared haloperidol and clozapine in patients with treatment-refractory schizophrenia (Rosenheck et al. 1997). This study was not designed as a relapse prevention trial, but rather as a comparison of the two agents in individuals who were poor responders to conventional therapy. However, the 1-year study is somewhat informative about the usefulness of the two drugs in patients living in the community. Fifty-seven percent of the patients taking clozapine completed the study, compared with only 28% of the patients taking haloperidol ($P < 0.001$). Using 20% improvement on the PANSS as the criterion for response, the investigators found that 42% of patients treated with clozapine and 31% of patients treated with haloperidol were responders ($P = 0.09$). In addition, clozapine-treated patients had fewer mean days of hospitalization (143.8 days) compared with haloperidol-treated patients (168.1 days; $P = 0.03$).

These studies are encouraging for a number of reasons. First, the VA study (Rosenheck et al. 1997) addressed the issue of whether clozapine's advantage in relapse prevention is only an effect of the monitoring system for agranulocytosis—that is, does the requirement for weekly blood tests act as a means of assuring compliance? Because the clozapine-treated and haloperidol-treated patients had the same blood monitoring, the advantage of clozapine appears to be an intrinsic effect of the drug. Also, clozapine is a drug that has its own discomforting side effects, including sedation, hypersalivation, constipation, and hypotension. These studies indicate that patients in long-term treatment are able to tolerate these effects.

Mania in Bipolar Disorder

Given that all available antipsychotics are effective in reducing manic symptoms, it is not surprising that clozapine is effective in bipolar mania. However, accumulating evidence suggests that clozapine is particularly effective for manic symptoms that are not responsive to other agents. McElroy et al. (1991) were among the first to observe clozapine's unique effects in patients with bipolar disorder. Subsequent studies have confirmed clozapine's effectiveness as monotherapy and as a supplementation medication for mania. In an open-label randomized trial in acutely manic patients (Barbini et al. 1997), clozapine was as effective as chlorpromazine and had a more rapid onset. Suppes et al. (1999) randomly assigned patients with schizoaffective and bipolar illnesses to either supplemental clozapine or treatment as usual during a 1-year open-label trial. Among both schizoaffective and bipolar patients, those treated with clozapine demonstrated greater improvements. Other prospective open-label studies (Calabrese et al. 1996; Green et al. 2000) confirmed clozapine's effectiveness in refractory bipolar illness. Although the available data support clozapine's effectiveness in mania, none of these trials has been double blind.

Depression With Psychotic Features

Limited evidence suggests that clozapine is effective as monotherapy and as an adjunctive treatment for patients with major depression with psychotic features. This evidence is currently confined to case reports with relatively small numbers of cases (Ranjan and Meltzer 1996; Rothschild 1996).

Psychosis in Parkinson's Disease

Psychosis with delusions and hallucinations occurs in approximately 25% of patients with Parkinson's disease (Wolters and Berendse 2001). These symptoms frequently appear in patients who are receiving dopaminomimetic drugs but may also occur as a result of a cholinergic deficit. Three double-blind studies (French Clozapine Parkinson Study Group 1999; Jones and Stoukides 1992; Parkinson Study Group 1999; Pollak et al. 2004) found that clozapine at doses as low as 25–50 mg was effective in reducing psychotic symptoms. Moreover, these doses were not associated with an increase in tremor and rigidity. A report from the American Academy of Neurology (Miyasaki et al. 2006) recommended clozapine as a preferred agent for psychosis in Parkinson's disease.

Schizophrenia in Children and Adolescents

Two randomized, controlled trials from the NIMH have evaluated the effectiveness of clozapine in childhood-onset schizophrenia. The first (Kumra et al. 1996) compared clozapine and haloperidol in individuals with a mean age of about 14 years who had done poorly on FGAs. Clozapine was superior for both positive and negative symptoms. A more recent double-blind study (Shaw et al. 2006) compared clozapine and olanzapine in subjects with a mean age of about 12 years. The results from this study were less clear. Although there were substantial differences favoring clozapine, the differences were only statistically significant for negative symptoms. The small sample (n = 12 for clozapine and n = 13 for olanzapine) was a limiting factor for obtaining statistical significance. Both studies found that this younger population appeared to be particularly vulnerable to clozapine's side effects. Nevertheless, these studies suggest an important role for clozapine in younger patients with schizophrenia with refractory symptoms.

SIDE EFFECTS AND TOXICOLOGY

Hematological Effects

The side effects of clozapine make it one of the most challenging medications for psychiatrists to prescribe. The main factor that limits its use is the potential serious side effect of agranulocytosis. Agranulocytosis is defined as a drop in absolute neutrophil count (ANC) to levels below 500/mm^3. In 1975, there were 17 cases of agranulocytosis in Finland, and widespread use of the medication for the treatment of schizophrenia was temporarily halted (Amsler et al. 1977; de la Chapelle et al. 1977). Agranulocytosis is a potentially lethal side effect that occurs in less than 1% of patients treated in the United States (Alvir et al. 1993). In the United States, all patients who are taking clozapine are entered into a national registry. Through the national registry, patients are prescribed the medication only if their WBC count shows no signs of clinically meaningful suppression (Honigfeld 1996). In a review of the morbidity and mortality of clozapine-treated patients (Honigfeld et al. 1998) over a 5-year period, 99,502 patients were registered through the Clozaril National Registry. Of these, 2,931 (2.95%) patients developed leukopenia (WBC count = 3,500/mm^3), and 382 (0.38%) patients developed agranulocytosis (ANC <500/mm^3). Twelve of the cases of agranulocytosis (0.012%) were fatal. These findings contrast with the 1%–2% cumulative incidence expected from the premarketing experience with clozapine. In the United States, 1,743 patients received the drug in premarketing trials. In addition, this estimate was based on trials in Europe performed in the 1970s and 1980s (Honigfeld et al. 1998). The encouraging report by Honigfeld et al. (1998) supports the monitoring system for clozapine as an adequate measure to prevent agranulocytosis.

The rates of clozapine-induced agranulocytosis in other parts of the world are similar to the rate in the United States (Gaszner et al. 2002; Helmchen 1989; Jungi et al. 1977). However, it is unclear what the rates are in parts of the world where generic medication is used and no registry exists. The onset of agranulocytosis occurs most often during the first 6 months of treatment and is usually marked by a gradual fall in WBC count, often over several weeks. A precipitous fall within 1 week can occur but is much less common (Honigfeld et al. 1998). Thus, patients must be monitored with weekly blood cell counts for the first 6 months and every 2 weeks thereafter. Various investigators have tried to

determine whether there are predictors of clozapine-induced agranulocytosis. Our group and others examined the possibility that agranulocytosis is immune mediated and thus preceded by eosinophilia. However, such a relationship has not been supported by our study or by others (Ames et al. 1996; Hummer et al. 1994). It has been observed that patients of Ashkenazi Jewish origin (Lieberman et al. 1990) are overrepresented among the cases of agranulocytosis, prompting researchers to examine whether there may exist a genetic predisposition for a particular immunohistocompatibility complex and/or immune response (Dettling et al. 2001). No clear relationship has been found, although speculations about human leukocyte antigen (HLA) types have been made, particularly HLA B38, in American Jews of Ashkenazi origin who develop agranulocytosis (Lieberman et al. 1990). In contrast, one Israeli study, composed of patients with non-Ashkenazi background, did not support this relationship (Meged et al. 1999).

When clozapine treatment is discontinued upon identification of marked leukopenia, patients usually recover within 14–24 days and without any long-term consequences. However, rechallenging patients who have experienced agranulocytosis almost always leads to reoccurrence of the problem. The onset of the second episode is more aggressive than the first. In nine patients who were known to be rechallenged, the average time to onset was 10 weeks shorter (14 weeks) than the first episode (24 weeks) (Safferman et al. 1992). Agranulocytosis has been successfully treated by discontinuing the medication, providing supportive measures, and administering granulocyte colony–stimulating factor, a medication that is commonly prescribed to patients with medical illnesses that precipitate WBC count suppression (Raison et al. 1994; Weide et al. 1992; Wickramanayake et al. 1995).

When clozapine first appeared on the market, mandatory monitoring of WBC levels each week was recommended for all patients taking clozapine. In January 2006, Novartis and the FDA notified clinicians of modifications to the recommended monitoring schedule for patients receiving clozapine (available at: www.pharma.us.novartis.com/product/pi/pdf/Clozaril.pdf).

Under the new monitoring guidelines, when a patient begins clozapine treatment, he or she must have a baseline WBC count of no less than 3,500/mm^3 and an ANC of no less than 2,000/mm^3. Weekly WBC and ANC levels must be taken for 6 months, at which time the frequency can be reduced to every 2 weeks, provided that treatment and monitoring have not been interrupted and WBC counts and ANCs have been within acceptable ranges. After 1 year, monitoring can be reduced to monthly blood tests. There are specific recommendations for intensified monitoring following discontinuation of clozapine therapy, particularly if therapy is interrupted because of blood dyscrasias.

Cardiac Effects

Well-known side effects of clozapine on the cardiovascular system include tachycardia and orthostatic hypotension. Tachycardia is thought to be attributable to the anticholinergic activity of the medication, whereas hypotension is due to α-adrenergic blockade. Reports of clozapine-associated myocarditis and cardiomyopathy have raised concern that clozapine may be associated with other forms of cardiovascular toxicity. In January 2002, Novartis reported that there had been 213 cases of myocarditis, 85% of which occurred at recommended dosages of clozapine within the first 2 months of therapy. The presence of eosinophilia in many of the reported cases indicates that an immunoglobulin E (IgE)–mediated hypersensitivity reaction may be involved (Killian et al. 1999). Novartis (2002) also reported 178 cases of clozapine-associated cardiomyopathy, 80% of which occurred in patients younger than 50 years. Almost 20% of the incidents resulted in death, an alarming figure that may reflect delay in diagnosis and treatment. The detection of cardiac toxicity is particularly challenging, because its manifestations (tachycardia, fatigue, and orthostatic hypotension) are frequently observed in clozapine-treated patients, particularly when alterations in dosage are made (Lieberman and Safferman 1992). The poor specificity of signs for cardiac toxicity demands that patients with any personal or family history of heart disease be identified, and the threshold for medical evaluation of patients developing respiratory and cardiovascular symptoms must

be low (Wooltorton 2002). The etiology of the myocarditis and cardiomyopathy remains unclear at this time.

Sudden death has been associated with both conventional antipsychotic treatment and treatment of patients with clozapine. A thorough review of the literature examining reports from 1970 to 2004 of cardiac side effects in patients on clozapine concluded that clozapine is associated with a low risk (0.015%–0.188%) of potentially fatal myocarditis or cardiomyopathy (Merrill and Goff 2005). The cause of the sudden death is unclear; it is probably secondary to ventricular arrhythmia and may be associated with sudden increases in clozapine dosage.

Double-blind clinical trials of antipsychotic medications given to manage agitated behavior in elderly patients with dementia supported the notion that a greater risk of sudden death is associated with use of these medications in older populations. As a result, the labeling of all antipsychotics, including clozapine, was updated to include a boxed warning of this risk. In 2006, the FDA issued a reminder that off-label use of clozapine for dementia-related psychosis in elderly patients is associated with an increased risk of sudden death. It is extremely important when raising the dosage of clozapine that incremental changes do not exceed 50 mg every 2 days (Worm et al. 1993). Clinicians must weigh the potential superb clinical benefit of clozapine against these cardiac risks. We recommend that an electrocardiogram be performed prior to initiation of clozapine.

For hypotension caused by clozapine, we also recommend a slow upward titration of the medication and monitoring of orthostatic vital signs during the first weeks of therapy. Patients should be educated about the risk of orthostatic hypotension and should be taught to rise slowly from supine positions. Concomitant treatment with β-blocking agents may be necessary for persistent tachycardia. However, the use of β-blockers may exacerbate the hypotensive effects of clozapine and should be used cautiously.

Metabolic Effects

Weight Gain

The metabolic side effects of clozapine are prominent (Henderson 2001; D. A. Wirshing et al. 1998, 1999). Weight gain has been observed in both premarketing and postmarketing trials (Henderson 2001; Simpson and Varga 1974). In patients observed in various clinical trials in our laboratory, the average weight gain in a 6-month period with clozapine treatment was 6.9 ± 0.8 kg. Allison et al. (1999) performed a meta-analysis of the weight-gain data in short-term trials of medications. The average weight gain observed with clozapine was 4.45 kg, which exceeded the weight gain observed with all of the other medications in the study, including the conventional agent thioridazine (3.19 kg), a medication known for its weight-gain liability. The weight gain observed with clozapine seems to occur for a prolonged period of time—up to 40 weeks. In one naturalistic study, Henderson (2001) observed patients in a clozapine clinic for 5 years and noted weight gain occurring for up to 46 months in some patients.

Body mass index (BMI; expressed in kg/m^2), which takes into account a patient's weight relative to his or her height, and waist-to-hip ratio (WHR) are important parameters to measure, because they both are predictors of cardiovascular risk. Obesity is defined as a BMI of 27 kg/m^2. Waist measurements of 102 cm (or >40 inches) in men and 88 cm (or >35 inches) in women are indicative of the metabolic syndrome and are strong predictors of diabetes and other medical complications, including heart disease and sleep apnea (D. A. Wirshing et al. 2002a, 2002c). Deposition of weight in the abdomen, in excess of weight on the hips (highly correlated with the development of diabetes), can also be assessed with the WHR. Frankenburg et al. (1998) examined BMI and WHR in 42 patients treated with clozapine. The majority of patients experienced increases in both of these parameters. In females, the authors observed an average WHR of 0.8 after 37 months of clozapine therapy, with a

significant average increase in BMI from 23.2 to 29.1 kg/m^2 (P = 0.001). Male subjects also gained weight and body mass. After 39 months of clozapine therapy, the average WHR in males was 0.93, with a significant average increase in BMI, from 26.4 to 29.7 kg/m2 (P <0.001). Both males and females in the sample became obese.

Phase 2 of CATIE provided an opportunity to compare weight gain among patients assigned to clozapine, olanzapine, risperidone, and quetiapine (McEvoy et al. 2006). The numbers of patients assessed in the analyses were small, with only 45 patients in the clozapine group, 17 in the olanzapine group, 14 in the quetiapine group, and 14 in the risperidone group. Although the differences in weight gain among these agents were not statistically significant, they were interesting, with patients on clozapine gaining a mean of 0.5 lb per month, compared with 1.0 lbs on olanzapine, –0.4 lb on quetiapine, and 0.5 lb on risperidone.

Researchers have tried to determine predictors of clozapine-associated weight gain. Of concern is that adolescents may be among the most vulnerable to this side effect. Theisen et al. (2001a, 2001b) reported that the prevalence of obesity in adolescent patients taking clozapine was 64% (n = 69). Others have speculated that clozapine-associated weight gain may be genetically determined, and several candidate genes are being explored (Basile et al. 2001). Numerous neurotransmitters and receptors are affected by clozapine. Specifically, we noted a logarithmic association between clozapine-associated weight gain and its effect on the histamine$_1$ (H_1) system (D. A. Wirshing et al. 1999). Other researchers have speculated that clozapine interferes with metabolism by interrupting the feedback loop between leptin, a hormone produced by adipose cells that should signal satiety to the brain, and neuropeptide Y, a peptide that is thought to stimulate appetite. Instead, patients treated with clozapine have been observed to have elevated levels of leptin (Bromel et al. 1998; Kraus et al. 1999; Melkersson and Hulting 2001).

Diabetes

The weight gain observed with clozapine can place patients at risk for significant health problems. Diabetes is naturally the most concerning potential sequela of this weight gain. Numerous case reports have linked clozapine with new-onset diabetes (D. A. Wirshing et al. 1998). In Henderson's (2001) naturalistic study of 81 patients observed over a 5-year time period, 36.6% of the patients developed diabetes. The prevalence of diabetes in the United States is estimated to be approximately 7%, with another 7% of cases undiagnosed. Koller et al. (2001) published the largest series of case reports submitted voluntarily to the FDA MedWatch Program. The report revealed that there were 2,424 new-onset cases, 54 of which were cases of diabetic exacerbations and 80 of which were cases of diabetic ketoacidosis, a potentially life-threatening condition. The average age of the patients in the report was 40 ± 12 years, and the male-to-female ratio was 2:1. Diabetes usually occurred within 6 months of starting clozapine. In our review of the peer-reviewed case literature, there seemed to be a preponderance of African Americans and males (D. A. Wirshing et al. 1998). As noted by Popli et al. (1997), there is a higher prevalence of non-insulin-dependent diabetes in African Americans compared with Caucasians in the United States, and this is likely the result of both nutritional factors and impaired access to health care. The significance of the overrepresentation of males is unclear but may reflect some hormonal interaction with glucose metabolism (Andersson et al. 1994)—or, more likely, selection bias, in which fewer women are placed on novel drugs.

We reviewed the charts of 590 patients taking antipsychotic medications and found statistically significant shifts in blood glucose among patients treated with clozapine and olanzapine, but not among patients treated with risperidone and quetiapine (D. A. Wirshing et al. 2002a). Sernyak et al. (2002) published a study examining the records of more than 30,000 patients in a VA database and found that the prevalence of the diagnosis of diabetes was higher among patients treated with novel antipsychotic medications than among patients treated with conventional agents. In particular, clozapine, olanzapine, and quetiapine were associated with much higher rates of diabetes than were

conventional agents for all age ranges, whereas risperidone was not associated with a higher diabetes prevalence. The etiology of diabetes in clozapine-treated patients remains unclear. The most likely mechanism is that clozapine-associated weight gain causes an increase in insulin resistance.

However, weight gain is often, although not always, seen in patients treated with novel antipsychotics who develop new-onset diabetes, although a literature review spanning the years 1975–2006 by Newcomer (2006) concluded that antipsychotic medication–associated adiposity is the main culprit in the development of diabetes. Thus, one potential mechanism of diabetes induction is an increase in adiposity that, in turn, leads to insulin insensitivity, glucose intolerance, and, if sufficiently severe, diabetes. This notion is supported by results from a small study by Yazici et al. (1998), who found that clozapine increased blood glucose, insulin, and C peptide, which suggests that glucose intolerance was due to increased insulin resistance. It is also speculated that clozapine directly affects beta cells of the pancreas (D. A. Wirshing et al. 1998). Recent evidence from animal studies suggests that clozapine dysregulates glucose metabolism by directly impairing the reaction of islet cells to glucose stimulation (Sasaki et al. 2006). Thus, the etiology of diabetes may be independent of adiposity, instead reflecting a direct effect of muscarinic blockade on the pancreatic islet cells.

Much of the information concerning the association of clozapine and diabetes mellitus is based on case reports, retrospective chart reviews, naturalistic studies, and cross-sectional studies. Although definitive studies have yet to be reported, the evidence is growing that clozapine may significantly impair glucose metabolism and increase the risk of diabetes in patients with schizophrenia. Diabetic ketoacidosis, although occurring infrequently, is of concern because of the risk of death. Patients treated with clozapine should be routinely screened for diabetes and other metabolic abnormalities, including raised lipid levels. Patients with risk factors for diabetes should be monitored more closely. Reports and clinical experience suggest that in a case of atypical antipsychotic–associated diabetes or diabetic ketoacidosis, discontinuation of the antipsychotic agent may result in reversal of the hyperglycemia and diabetes. During clozapine therapy, we recommend monitoring fasting glucose, cholesterol, and lipids at baseline and every 6 months thereafter.

Prevention of weight gain with clozapine, through nutrition and diet counseling, is recommended. Caloric restriction and exercise for 30 minutes per day should be recommended. Screening questions by physicians that we find useful include the following: "Have you noticed if your belt or pants size has changed?" "Have you noticed an increase in thirst or urinary frequency?" We strongly recommend weighing patients at each visit and monitoring blood pressure.

Dyslipidemias

Compelling data indicate that clozapine treatment is associated with dyslipidemias. Ghaeli and Dufresne (1996) performed a retrospective review of data from 24 male and 15 female patients treated with clozapine and 13 male and 15 female patients treated with typical antipsychotics (primarily high-potency agents). All patients had been taking these agents for at least 1 year. Age and gender of the patient, concomitant medications taken, and antipsychotic dosages were used as covariates in the analyses. Patients taking clozapine demonstrated significantly higher triglyceride levels than did patients taking typical agents (mean triglyceride level of 264.6 mg/dL for patients in the clozapine group vs. 149.8 mg/dL for patients taking typical agents; $P < 0.001$). A retrospective chart review by Gaulin et al. (1999) compared 117 patients taking clozapine with 45 patients taking haloperidol. The study found significant increases in triglyceride levels for both men and women taking clozapine—a mean increase from 184.6 mg/dL to 273.4 mg/dL for men ($P < 0.01$) and from 164.9 mg/dL to 223.3 mg/dL for women ($P < 0.05$).

Spivak et al. (1999) reported on a retrospective data from 70 patients being treated with clozapine for 6 months. They observed a significant increase in triglyceride levels from 69.6 mg/dL prior to the initiation of clozapine to 77.3 mg/dL just 6 months after initiation ($P < 0.05$). This suggests not only

that clozapine can increase triglyceride levels but also that it can do so over a relatively short period of time. Another prospective sample of 8 clozapine-treated patients showed an 11% increase in triglyceride levels ($P < 0.05$) after 12 weeks of clozapine therapy at an average dosage of 352 mg/day. No significant changes in total cholesterol, low-density lipoprotein (LDL) cholesterol, or high-density lipoprotein (HDL) cholesterol were observed (Dursun et al. 1999). More recently, patients who received clozapine in Phase 2 of CATIE demonstrated greater elevations in both triglycerides and cholesterol than patients on olanzapine, risperidone, or quetiapine (McEvoy et al. 2006). However, these differences were not statistically significant.

Our group published the first study to compare multiple SGAs (clozapine, risperidone, olanzapine, and quetiapine) against each other and against the typical agents fluphenazine and haloperidol in their propensity to affect lipid parameters (D. A. Wirshing et al. 2002a). This study was a retrospective review of the charts of 215 patients taking antipsychotics (clozapine, olanzapine, risperidone, quetiapine, haloperidol, or fluphenazine). Lipid data from 2.5 years before and after initiation of the target antipsychotic were collected. Covariates used in the analysis included age of patient, duration of antipsychotic treatment, concomitant use of other medications that could affect lipids, and initial laboratory values. Patients receiving clozapine or olanzapine demonstrated statistically significant increases in triglyceride levels compared with the other groups. Triglyceride levels increased by more than 30% for patients taking clozapine or olanzapine, compared with only a 19% increase for patients taking risperidone; patients taking haloperidol or fluphenazine developed decreases in triglyceride levels.

The clinical implications of these findings are thought-provoking—for example, could triglyceride elevation account for the beneficial psychiatric effect of these medications through stabilization of neuronal membranes? Some authors have suggested that changes in triglycerides may actually affect serotonergic activity. Diebold et al. (1998) postulated that elevated triglyceride levels cause increases in brain cell membrane fluidity, which in turn lead to increased presynaptic reuptake of serotonin and decreased postsynaptic serotonergic function. This effect on triglycerides may enhance the ability of SGA medications such as clozapine to inhibit serotonergic activity and thus may contribute to their mechanism of action (Kingsbury et al. 2001). Studies have also shown correlations between elevations in triglyceride levels and changes in mood. For example, increases in triglyceride levels have been shown to be associated with decreased hostility (Diebold et al. 1998). Spivak et al. (1998) observed that patients taking clozapine who developed increases in triglycerides also demonstrated decreases in aggression and suicidal behavior in comparison with patients taking typical antipsychotics, although the difference was not significant ($P = 0.07$). Muldoon et al. (1990) reviewed numerous randomized clinical trials that focused on reducing lipid levels for primary prevention of coronary artery disease. They concluded that the risk of death due to accidents, suicide, or violence was significantly higher in patients with reduced lipid levels ($P = 0.004$).

The overall impact of clozapine—and of virtually all other antipsychotic medications—on lipids, glucose, and obesity may result in an increase in the prevalence of the metabolic syndrome. The term *metabolic syndrome* describes a set of risk factors for diabetes, heart disease, and cerebrovascular disease. According to the National Cholesterol Education Program and American Diabetes Association criteria (Lamberti et al. 2006; Meyer et al. 2006), metabolic syndrome is defined as the presence of three or more of the following:

- Waist circumference >102 cm for men and >88 cm for women
- Fasting blood triglyceride level ≥150 mg/dL
- HDL cholesterol level <40 mg/dL for men and <50 mg/dL for women
- Blood pressure ≥130 mm Hg systolic or ≥85 mm Hg diastolic
- Fasting blood glucose level ≥100 mg/dL

To examine whether the medical consequences of obesity may offset the lifesaving benefits gained

from clozapine's potentially decreased suicide rate, Fontaine et al. (2001), using mathematical modeling, estimated that 492 suicide deaths per 100,000 schizophrenia patients would be prevented over 10 years with the use of clozapine. This was compared with an estimated 416 additional deaths due to antipsychotic-induced weight gain. Although this estimate is mathematically based and somewhat controversial, these investigators suggest that the lives saved by clozapine may essentially be offset by the deaths associated with weight gain. Thus, it behooves physicians prescribing clozapine to monitor weight, glucose, and lipids—we recommend obtaining measurements at the onset of therapy and every 6 months thereafter—to assist in minimizing the increased risks for coronary artery disease to which our patients are already predisposed.

In 2004, in response to growing concern that the majority of antipsychotic medications may be associated with weight gain and other metabolic changes, the American Diabetes Association and other groups published a set of guidelines for monitoring weight, glucose, and lipids (American Diabetes Association et al. 2004). Also in 2004, a very comprehensive literature review was conducted by Marder et al. (2004) to provide guidance to clinicians regarding monitoring of weight, glucose, lipids, and other parameters of physical health in patients with schizophrenia. Labeling changes were made for all antipsychotic medications, including clozapine, regarding these metabolic risk factors.

Seizures

A well-known risk of clozapine treatment is the risk for seizures, which are thought to occur in 5%–10% of patients treated with this medication (Welch et al. 1994). The cause of seizures is unclear, but it is generally thought that rapid escalations in dosage and possibly high plasma levels of clozapine may account for the development of seizures (Klimke and Klieser 1995). Clozapine-associated seizures occur most often at dosages greater than 600 mg/day. The relationship between clozapine plasma levels and seizures is somewhat inconsistent in the literature (Simpson and Cooper 1978; Vailleau et al. 1996). Some speculations as to whether the therapeutic efficacy of clozapine lies in its ability to induce subcortical seizure-like activity have been put forth by Stevens and colleagues (Stevens 1995; Stevens et al. 1996), who proposed that the amino acid neurotransmitter system might include naturally occurring anticonvulsants that suppress signal transduction and ultimately lead to information-processing deficits. According to this hypothesis, the emergence of electroencephalogram (EEG) abnormalities would correspond to an increase in signal transduction and improved information processing.

In addition to seizure risk, several researchers have observed that EEG abnormalities, such as slowing, occur in the majority of patients treated with clozapine (Welch et al. 1994). Slowing may be attributable to the anticholinergic activity of this medication. Because patients with schizophrenia often have EEG abnormalities (some estimated rates are 25%), it is unclear whether a baseline EEG would predict whether a particular patient would develop seizures when given clozapine. On the basis of their experience with clozapine in treating patients with refractory illness, Welch et al. (1994) proposed guidelines that recommend increased monitoring for patients with abnormal baseline EEGs. Our own experience leads us to recommend obtaining a baseline EEG when initiating clozapine treatment in patients who have a history of possible head injury, loss of consciousness, or other risk factors for seizures. In cases where EEG abnormalities are found, we still believe that clozapine treatment is warranted, but it would be best if treatment were initiated with prophylactic anticonvulsant medication.

The anticonvulsant agents sodium valproate, gabapentin, and topiramate have been used successfully to treat clozapine-induced seizures (Navarro et al. 2001; Toth and Frankenburg 1994; Usiskin et al. 2000). Topiramate has an advantage over sodium valproate in that it is associated with very little weight gain. In cases in our clinic where patients have developed seizures while taking clozapine, we institute rapid loading with anticonvulsant medication and temporarily discontinue the clozapine treatment. We then slowly reintroduce and retitrate the clozapine once the patient is taking an

adequate dose of anticonvulsant medication.

Constipation

A truly problematic consequence of clozapine's anticholinergic activity is its propensity to cause significant constipation. This can be a difficult side effect to manage in severely mentally ill individuals, who may not complain about the problem until a medical emergency, such as acute bowel obstruction, occurs. In institutional settings and in prisons, where patients may have little access to exercise and where monitoring of patients' fluid intake is not performed, constipation from clozapine can be serious or even fatal (Drew and Herdson 1997; Hayes and Gibler 1995; Levin et al. 2002). Typically, constipation can be avoided by proactive modifications in patients' diets and education about adequate fluid intake and exercise. The medical treatment that we favor is prophylactic therapy with sorbitol. We are less inclined to recommend treatments involving bulking agents, particularly in the setting of poor fluid intake. High-fiber diets can also be beneficial.

Other Side Effects

Sedation is one of the most difficult and common side effects of clozapine to manage. Patients often do not want their doses increased in the setting of increased sedation and will complain of sedation as one of the most annoying consequences of clozapine treatment (Angermeyer et al. 2001). In our experience, sedation is usually the limiting factor controlling both the rate at which the dosage of clozapine can be increased and the maximum dosage the patient can tolerate. However, no rigorous studies have been published.

There have been several reports of respiratory arrest or depression during the early stages of treatment with clozapine (Novartis 2002). Two of the patients who experienced respiratory arrest were concomitantly taking benzodiazepines.

Sialorrhea is a commonly reported side effect of clozapine (occurring in over 50% of patients) that can be problematic for patients. The etiology of sialorrhea is unclear, but the condition does not seem to be caused by the dopamine blockade. It may be mediated through α-adrenergic receptor blockade. Case series and small pilot studies indicate that treating sialorrhea with antiadrenergic agents, such as the clonidine patch, or anticholinergic agents, such as benztropine and intranasal ipratropium bromide, may be successful (Calderon et al. 2000). We generally recommend that patients sleep with a towel on their pillow, as this side effect seems to be most bothersome during the night. Unfortunately, the use of concomitant antiadrenergic or anticholinergic agents adds to the potential side-effect burdens of hypotension and constipation, respectively.

Neuroleptic malignant syndrome (NMS), a syndrome of unknown etiology that includes hyperthermia, autonomic instability, and severe rigidity, has been reported in several patients treated with clozapine (Anderson and Powers 1991). The etiology of NMS that occurs in the context of clozapine use, as well as that occurring with use of conventional antipsychotics, remains unclear.

Hepatotoxicity has been reported with clozapine, especially in the setting of polypharmacy (Macfarlane et al. 1997; W. Wirshing et al. 1997). Asymptomatic elevation of transaminase levels was observed most commonly, affecting between 30% and 50% of patients treated with clozapine. Icteric hepatitis was uncommonly seen in Macfarlane et al.'s (1997) review of clozapine-related hepatotoxicity and was noted in 84 of 136,000 patients (0.06%). Fatal acute fulminant hepatitis has been documented in 2 patients (0.001%). Although serious toxicity is rare, prescribers of clozapine should be aware of its hepatotoxic potential.

Sexual side effects, including priapism and impotence, have been reported with clozapine. Urinary retention and bladder dysfunction can also result from clozapine. In a study surveying patients' sexual side effects, we found that clozapine-treated patients actually had fewer sexual complaints than patients on other antipsychotic medications (prolixin and risperidone) (D. A. Wirshing et al. 2002b).

Although this daunting array of side effects—along with the management of the risk of agranulocytosis—makes the treatment of patients with clozapine complex, it is common for patients to report a sense of relief from the dysphoric moods they experienced while taking conventional drugs. Additionally, the freedom from EPS may account for the enhanced sense of well-being in patients treated with clozapine.

DRUG–DRUG INTERACTIONS

As previously mentioned, clozapine is predominately metabolized by cytochrome P450 (CYP) 1A2, although CYP2D6 and CYP3A3 also contribute to its metabolism (Buur-Rasmussen and Brosen 1999). Smoking, which induces CYP1A2, lowers clozapine plasma levels. Fluvoxamine, a potent inhibitor of CYP1A2, dramatically increases plasma levels of clozapine (Heeringa et al. 1999), and on occasion, adverse effects are seen (Koponen et al. 1996). This phenomenon can lead to clozapine intoxication in patients receiving high doses of fluvoxamine. Other reports suggest that inhibitors of CYP2D6, including paroxetine and fluoxetine, can elevate clozapine levels (Joos et al. 1997; Spina et al. 1998).

CONCLUSION

Clozapine maintains an important place in the treatment of severe psychosis. Side effects, including agranulocytosis, seizures, sedation, and weight gain, make it the most difficult antipsychotic to prescribe. As a result, clozapine should be reserved for patients who have failed to respond to other SGAs. The difficulty in administering clozapine has led many patients and their clinicians to resist its use. This is unfortunate, because patients should never be deemed "treatment refractory" or "partial responders" until they have received an adequate trial of clozapine.

Chapter 29. Olanzapine

HISTORY AND DISCOVERY

The story of specific antipsychotic medications for patients with schizophrenia and other severe psychiatric illnesses began in the early 1950s, when chlorpromazine was first given to psychotic patients in France (Delay and Bernitzer 1952). The antipsychotic qualities of this compound, as well as its "tranquilizing" effect, were dramatic and substantial. Studies performed around the world during the 1950s showed the usefulness of this new compound and the others that followed. As is well known, multicenter trials of antipsychotic medications found that the approved medications were substantially and significantly better than placebo (Cole et al. 1964). Furthermore, despite the range of chemical structures, the clinical effects were similar. In addition, the need to investigate the new medications for psychiatric illness led to improved clinical trial methodology for the field. During the 1960s, randomized and placebo-controlled trials became the standard for assessing the new medications for schizophrenia. These trials led to the neuroleptic medications becoming the standard somatic treatment for schizophrenia.

However, over time, the adverse effects of the neuroleptic medications began to be recognized as more troublesome (Table 29–1). For example, most patients complained of iatrogenic parkinsonism, dystonias, slowed thinking, blunted affect, akathisia, and tardive dyskinesia. These side effects were uncomfortable for patients taking the neuroleptic medications and, in many cases, led to poor adherence with treatment.

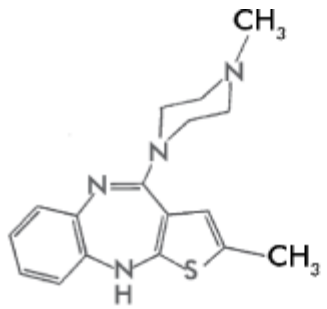
In addition to the adverse effects of the neuroleptic medications, continued research of the neuroleptics indicated that a substantial number of patients were not fully treated (Angrist and Schulz 1990). Therefore, the field had the problem of an intervention that was not useful for all patients and was uncomfortable to take for many patients whose symptoms did respond.

Studies with the first atypical antipsychotic medication, clozapine, began in the late 1960s, although the compound was initially discovered in 1961. This interesting agent led to decreases in symptoms of psychosis without causing movement disorder side effects. Trials were moving forward in Europe (Povlsen et al. 1985) and the United States (Shopsin et al. 1979) when reports of agranulocytosis

resulting in the death of some subjects first appeared (Amster et al. 1977). These unfortunate outcomes stopped research of clozapine essentially in its tracks. However, the hope for the development of an atypical antipsychotic medication did not die with these early studies of clozapine. Eventually, clozapine was approved as a treatment of last resort for schizophrenia, and its use must be accompanied by rigorous medical follow-up (Kane et al. 1988).

Concurrent with this research, investigators at Eli Lilly were screening numerous compounds for psychotropic properties. In 1990, the company applied for and received a patent for the compound olanzapine. It is interesting to note that the new compound had many structural similarities to clozapine and was thought to have potential for schizophrenia, mania, and anxiety.



Olanzapine was first given to patients with schizophrenia in 1995 (Baldwin and Montgomery 1995). The patients in the study had a substantial decrease in their symptoms while receiving 5–30 mg/day of the compound. The authors noted a low degree of extrapyramidal side effects (EPS), although concern was raised for elevation of liver enzymes, as one patient had to discontinue the study for that reason.

The initial testing of olanzapine had useful results and led to a program of four pivotal trials of olanzapine. These first four controlled studies examined the differences between olanzapine (10 mg/day fixed dose) and placebo (Beasley et al. 1996a), olanzapine and haloperidol or placebo (Beasley et al. 1996b), olanzapine (low, medium, or high dose) and olanzapine 1.0 mg/day or haloperidol 15 mg/day (Beasley et al. 1997), and olanzapine and haloperidol in a large international study (Tollefson et al. 1997). The positive results for olanzapine led to U.S. Food and Drug Administration (FDA) approval in 1997 and then widespread use in the United States and around the world.

STRUCTURE–ACTIVITY RELATIONS

Olanzapine is a thiobenzodiazepine derivative (Figure 29–1) that bears a close structural resemblance to clozapine. The formal chemical name of olanzapine is 2-methyl-4-(4-methyl-1-piperazinyl)-10*H*-thieno[2,3-*b*] [1,5]benzodiazepine. Structurally, it differs from clozapine by two additional methyl groups and the lack of a chloride moiety. This similarity leads to a relative similarity in the in vitro receptor binding profiles. According to the package insert, olanzapine is known to have a high affinity for selective dopaminergic, serotonergic (5-HT), histaminergic (H), and α-adrenergic receptors, with weaker affinity for muscarinic (M) receptors and weak activity at benzodiazepine (BZD), γ-aminobutyric acid type A ($GABA_A$), and β-adrenergic receptors (Eli Lilly 2006).

PHARMACOLOGICAL PROFILE

In vitro and preclinical behavioral studies of olanzapine predicted significant antipsychotic activity

with a low propensity to induce EPS. Because clozapine is the prototype for second-generation antipsychotic action, similarity to its effects relative to those of classic antipsychotics is evidence for the "atypicality" of comparator compounds such as olanzapine.

One possible mechanism for lowering risk for EPS is nonselective dopamine receptor binding. Classic antipsychotics selectively block D_2-like (D_2, D_3, and D_4) receptors over D_1-like (D_1 and D_5) receptors—for example, haloperidol has a D_2-to-D_1 binding ratio of 25:1. Clozapine nonselectively binds all five dopamine receptor subtypes, with a D_2-to-D_1 ratio of 0.7:1, whereas olanzapine is only partially selective for the D_2-like group, with a D_2-to-D_1 ratio of approximately 3:1, intermediate between those of haloperidol and clozapine.

Antipsychotics have traditionally been most effective in treating the positive symptoms of schizophrenia, including delusions, hallucinations, and the agitation brought on by these symptoms. The hallmark of second-generation or atypical antipsychotics is a decreased propensity to cause EPS. "Atypicality" has generally been used to refer to agents with reduced risk of EPS. Olanzapine has a low tendency to induce catalepsy, once regarded as a marker of antipsychotic efficacy but now seen as an indicator of a drug's likelihood of producing EPS (Fu et al. 2000).

In animal models predictive of antipsychotic efficacy, olanzapine produces effects indicating dopamine antagonism, with a low propensity to produce EPS. For example, in rats, olanzapine reduces climbing behavior induced by apomorphine and antagonizes stimulant-induced hyperactivity, both characteristic of antipsychotic effect. The ratio of the dose needed to produce catalepsy to the dose needed to inhibit conditioned avoidance, another model for atypical efficacy, is higher for olanzapine than for conventional agents, a circumstance that also denotes "atypicality" (Moore 1999).

Another potential mechanism whereby dopamine antagonists may exert antipsychotic effects with minimal EPS is through selective activity in the A10 dopaminergic tracts from the ventral tegmentum to mesolimbic areas compared with effects antagonizing the A9 nigrostriatal projections that mediate EPS. Olanzapine in chronic administration, like clozapine, selectively inhibits firing of A10 neurons without significant inhibition of A9 tracts (Stockton and Rasmussen 1996a). The nigrostriatal tract has often been implicated in EPS, whereas the limbic system has been associated with the positive symptoms of schizophrenia. Olanzapine shows increased c-fos activity in the nucleus accumbens relative to the dorsolateral striatum, thus demonstrating selective blockade of the mesolimbic dopamine tract compared with the nigrostriatal tract (Robertson and Fibiger 1996).

The current leading theory regarding atypicality relates to the fleeting effects of atypical antipsychotics at the D_2 receptor, coupled with regional selectivity of these compounds (Seeman 2002).The 5-HT_{2A} receptor in the nigrostriatal tract was once theorized to provide increased dopaminergic activity in that tract, thus sparing one from the parkinsonism frequently seen with conventional antipsychotics. However, this theory of atypicality is generally falling out of favor. Whereas olanzapine shows higher affinity for 5-HT_{2A} receptors than for D_2 receptors, the tight binding of serotonergic neurons does not show any influence on dopamine receptor blockade, and olanzapine still has a dopamine receptor saturation that is sufficient to produce antipsychotic activity and, at high enough doses, also strong enough to cause EPS (Kapur et al. 1998, 1999). Olanzapine has been shown to have a D_2 receptor occupancy saturation that is between that of clozapine and haloperidol and may be responsible for a decreased risk of EPS (Tauscher et al. 1999). However, as the current second-generation antipsychotic medications have substantially differing effects at all of these targets thought to play a role in atypicality, consensus is not there regarding the true rationale for atypicality compared to the first-generation antipsychotics (Farah 2005).

Amphetamine administration in rats is often used as a model for psychosis. The sympathomimetic activity and dopamine release provide a target for testing antipsychotic medications. Olanzapine disrupts the activity of amphetamines in rats (Gosselin et al. 1996). Olanzapine was shown in a rat

model to decrease dopamine release in the A10 dopaminergic neurons of the ventral tegmentum greater than the A9 dopaminergic neurons of the striatum after chronic administration and after an amphetamine challenge (Stockton and Rasmussen 1996a, 1996b). Olanzapine does not induce catalepsy in rats at doses needed for antipsychotic efficacy.

Another model of psychosis in rats is the administration of the glutamatergic *N*-methyl-D-aspartic acid (NMDA) receptor antagonist phencyclidine (PCP). Chronic PCP use in humans is associated with similar symptoms to schizophrenia, including negative symptoms, thus making it a putative model for schizophrenia (Krystal et al. 1994). Second-generation antipsychotics have been shown to enhance glutamatergic neurotransmission in pyramidal cells of the prefrontal cortex compared with first-generation antipsychotics (Ninan et al. 2003a). Olanzapine has been shown to decrease the hyperactivity of NMDA receptors under chronic PCP administration, which may have a bearing on the effect on negative symptoms (Ninan et al. 2003b). With chronic administration, glutamatergic activity continues to be affected by olanzapine (Jardemark et al. 2000). Despite these findings, olanzapine has no direct affinity for the NMDA receptor (Stephenson and Pilowsky 1999).

Effects on other systems show that olanzapine has a broad range of neurotransmitter effects. Although olanzapine has potent muscarinic M_{1-5} receptor affinity in vitro (another contributor to putative anti-EPS effects), in practice few patients have anticholinergic side effects that are clinically significant. α_1-Adrenergic and H_1 histaminergic antagonism contribute to the adverse-effect profile of orthostatic hypotension (α_1), sedation (H_1), and possibly weight gain (H_1). Olanzapine has little or no effect on α_2- and β-adrenergic, H_2, nicotinic, GABA, opioid, sigma, or benzodiazepine receptors.

PHARMACOKINETICS AND DISPOSITION

Olanzapine is well absorbed after oral administration, with peak concentrations in most people occurring 4–6 hours after ingestion (Kassahun et al. 1997). Approximately 40% of a given dose undergoes first-pass metabolism and therefore does not reach the systemic circulation, and food has little effect on olanzapine's bioavailability (Callaghan et al. 1999; Eli Lilly 2006; Kassahun et al. 1997).

Two bioequivalent oral formulations of olanzapine are currently available: a standard oral tablet and an oral disintegrating tablet. The oral disintegrating tablets are intended for swallowing and absorption through the gut; however, sublingual administration has also been favored by some. Markowitz et al. (2006) discovered that while the oral disintegrating preparation of olanzapine is more quickly absorbed than a standard oral tablet, it is absorbed at an equal rate if taken sublingually or if swallowed conventionally. In either case, the onset of action with the oral dissolving tablet is faster than with the standard oral tablet. After a 12.5-mg oral dose of ^{14}C-labeled olanzapine, approximately 57% of the radiocarbon was recovered in urine and 30% in feces. In vitro studies suggest that olanzapine is approximately 93% protein bound, binding primarily to albumin and α_1-acid glycoprotein (Kassahun et al. 1997).

Olanzapine is also available as an intramuscular preparation, intended for treatment of the acute agitation typically seen in schizophrenia or acute manic episodes of bipolar disorder. The peak plasma concentration is typically reached between 15 and 45 minutes after administration. The potency of intramuscular olanzapine is nearly five times greater than that of orally administered drug, based on plasma levels. Clinical antipsychotic onset with intramuscular olanzapine is evident within 2 hours of administration, with benefits lasting for at least 24 hours (Kapur et al. 2005).

Olanzapine is currently being tested in a long-acting injectable preparation composed of a dihydrate form of olanzapine pamoate. As a dihydrate molecule, it is less soluble in water than a monohydrate and thus has the longer half-life required for a depot formulation. This formulation is currently being evaluated in studies with a dosage schedule of once every 4 weeks (Mamo et al. 2008).

Finally, olanzapine is available in a combined preparation with fluoxetine. The olanzapine–fluoxetine

combination (OFC) tablet provides fixed doses of olanzapine and fluoxetine to enhance adherence to a regimen that includes both an antipsychotic agent and an antidepressant. Overall, there are few pharmacokinetic differences from adding fluoxetine to olanzapine, and those present are generally related to cytochrome P450 (CYP) 2D6 inhibition. There is no change in the overall half-life of olanzapine. While there are minor yet statistically significant differences in the concentration of olanzapine when taken in combination with fluoxetine, these changes are not clinically significant and do not change the side-effect profile of olanzapine (Gossen et al. 2002).

Olanzapine is extensively metabolized to multiple metabolites but primarily to 10-*N*-glucuronide and 4'-*N*-desmethylolanzapine (Macias et al. 1998). After long-term administration, average plasma concentrations for these metabolites are 44% and 30% of olanzapine concentrations, respectively (Callaghan et al. 1999). Other metabolites include 4'-*N*-oxide olanzapine and 2-hydroxymethyl olanzapine (Kassahun et al. 1997). In vitro studies assessing the oxidative metabolism of olanzapine suggest that CYP1A2 is the enzyme primarily responsible for the formation of 4'-*N*-desmethylolanzapine, flavin-containing monooxygenase-3 (FM03) is responsible for the formation of 4'-*N*-oxide olanzapine, and CYP2D6 is the primary enzyme responsible for the formation of 2-hydroxymethyl olanzapine (Ring et al. 1996b). Although CYP1A2 appears to be a major route of metabolism, olanzapine clearance in one study was not significantly correlated with salivary paraxanthine-to-caffeine ratio (thought to be a measure of CYP1A2 activity) (Hagg et al. 2001). Another analysis, however, found that the 4'-*N*-desmethylolanzapine–to–olanzapine plasma metabolic ratio significantly correlated with olanzapine clearance (Callaghan et al. 1999). Olanzapine pharmacokinetic parameters do not differ significantly between extensive and poor metabolizers of CYP2D6 (see Hagg et al. 2001).

Olanzapine shows linear pharmacokinetics within the recommended dosage range (Aravagiri et al. 1997; Bergstrom et al. 1995; Callaghan et al. 1999). Peak mean olanzapine concentrations after 8 days of olanzapine at 7.5 mg/day in 12 healthy males (11 smokers) were 18.3 ng/mL. Mean half-life was 36 hours, mean clearance was 29.4 L/hour, mean volume of distribution was 19.2 L/kg, and area under the concentration-time curve over 24 hours (AUC_{0-24}) was 333 ng*hour/mL. The half-lives of the two major metabolites (4'-*N*-desmethylolanzapine and 10-*N*-glucuronide) were 92.6 and 39.6 hours, respectively, and their AUC_{0-24} were 57 ng*hour/mL and 112 ng*hour/mL (Macias et al. 1998). Other analyses also have found the mean half-life of olanzapine to be approximately 30 hours and the mean apparent clearance to be approximately 25 L/hour (Callaghan et al. 1999; Eli Lilly 2006; Kassahun et al. 1997). Once-daily administration of olanzapine produces steady-state concentrations in about a week that are approximately twofold higher than concentrations after single doses (Callaghan et al. 1999). An in vitro study suggested that olanzapine may be an intermediate substrate of P-glycoprotein (Boulton et al. 2002). In a recent study, Mitchell et al. (2006) compared the pharmacokinetics of a 10- to 20-mg olanzapine dosage with that of a 30- to 40-mg dosage. Both dosages showed similar pharmacokinetic profiles and general tolerability, although akathisia was noted to be slightly higher in the high-dose group.

The clearance of olanzapine is generally decreased in women. Clearance of olanzapine is approximately 25%–30% lower in women than in men, based on results of population pharmacokinetic analyses (Callaghan et al. 1999; Patel et al. 1995, 1996). A study of 20 male and 7 female patients with schizophrenia receiving olanzapine also found that women had higher trough concentrations (29 ng/mL vs. 19 ng/mL) after receiving 1 week of olanzapine 12.5 mg/day; they continued to have higher plasma concentrations than men after the dosage was increased to 25 mg/day, with average week 8 plasma concentrations of 65 ng/mL and 35 ng/mL in women and men, respectively (Kelly et al. 1999). Despite the differences in clearance and plasma levels, there is no difference between sexes in incidence of EPS or other movement disorders (Aichhorn et al. 2006).

Olanzapine's pharmacokinetics in the elderly and in children have been noted to differ from that in

adults. In the elderly, olanzapine clearance is approximately 30% lower than in younger individuals, and the half-life is approximately 50% longer (Callaghan et al. 1999; Patel et al. 1995). A study of eight children and adolescents (ages 10–18 years) found pharmacokinetic parameters similar to those reported in nonsmoking adults, with an average T_{max} (time required to reach the maximal plasma concentration) of 4.7 hours, an average apparent oral clearance of 9.6 L/hour, and an average half-life of 37.2 hours (Grothe et al. 2000). In this study, patients could receive olanzapine dosages of up to 20 mg/day. The highest concentrations were seen when smaller-sized patients received dosages greater than 10 mg/day; therefore, dosing should take into consideration the size of the child.

Impairment in either hepatic or renal function has not been associated with altered olanzapine disposition. In a study of four healthy individuals and eight patients with hepatic cirrhosis, no significant differences in olanzapine pharmacokinetics were found, although urinary concentrations of olanzapine 10-*N*-glucuronide were increased in patients with cirrhosis (Callaghan et al. 1999). A study comparing olanzapine pharmacokinetics in six subjects with normal renal function, six subjects with renal failure who received an olanzapine dose 1 hour before hemodialysis, and six subjects with renal failure who received an olanzapine dose during their 48-hour interdialytic interval did not find any significant differences. In subjects receiving olanzapine 1 hour before hemodialysis, olanzapine was not detected in the dialysis fluid, suggesting that hemodialysis does not remove significant quantities of olanzapine. These data suggest that olanzapine dosage does not need to be adjusted in patients with renal or hepatic disease (Callaghan et al. 1999).

MECHANISM OF ACTION

In discussing the mechanism of action for olanzapine in the treatment of schizophrenia, it should be noted that there is no established molecular mechanism to unify the symptoms of schizophrenia. No precise animal or in vitro model for the illness exists, nor is there a consensus on the precise etiology or pathophysiology. Numerous neurochemical hypotheses exist, including abnormalities in dopaminergic, glutamatergic, serotonergic, and other systems such as neurotensin (Boules et al. 2007) and neuregulin (Benzel et al. 2007). Furthermore, other theories about the etiology and pathophysiology of schizophrenia include the possibility of abnormal development of the brain resulting in postulated changes in the relation of one part of the brain to the other (e.g., the prefrontal cortex to limbic areas) (Weinberger 1987). Further complicating these theories of pathophysiology of schizophrenia has been the understanding of the multiple different types of receptors for the same neurotransmitters that exist in the brain. Therefore, it is no longer possible to simply discuss hypotheses such as increased dopamine as a comprehensive theory for the etiology of schizophrenia.

Despite the caveats noted above regarding the rudimentary knowledge of the nature of schizophrenia, it is important to note that all approved antipsychotic medications have an important effect on the dopaminergic system, largely through the blockade of D_2 receptors (Kapur and Remington 2001). Even though there are substantial differences in affinities to the D_2 receptor among the traditional antipsychotic medications and the atypical antipsychotics, they all are full antagonists or are partial agonists at the D_2 receptor. Of interest is the evolving research indicating the importance for blockade of other receptors by the atypical antipsychotic medication class. As these systems have been investigated in the neuropsychopharmacology of schizophrenia, evidence is emerging that the action of second-generation antipsychotics, and olanzapine specifically, may improve different parts of the schizophrenia syndrome through effects on 5-HT receptors, by multiple-receptor binding, by region-specific and more fleeting binding to dopamine receptors, by effects on glutamate neurotransmission, and perhaps by influence on neuroprotein neurotransmitters. Each of these specific ideas for the mechanism of action of olanzapine is discussed in order.

As has been noted in the section on history of the development of olanzapine, innovations in the production of antipsychotic medications that cause fewer movement side effects have been a major advance clinically. One of the first theories about the mechanism of atypicality was the

5-HT–dopamine antagonist hypothesis (Meltzer et al. 1989). By comparing the ratio of 5-HT_{2A} to dopamine receptor blockade, these groups showed that the agents with greater relative 5-HT receptor blockade were in the atypical group, whereas those with greater relative dopamine receptor blockade were more likely to be in the typical group. Both in vitro and in vivo studies have clearly reported that olanzapine has a substantially greater ability to block 5-HT_{2A} receptors than dopamine receptors (Kapur et al. 1998).

For several years, psychopharmacological research on schizophrenia focused on finding drugs that block specific receptors. In the area of schizophrenia, medications such as pimozide, which has very few nondopaminergic properties, were thought to focus on the specific etiology and pathophysiology of schizophrenia. Therefore, it was somewhat surprising that the first atypical antipsychotic medicine, clozapine, was a multiple-receptor blocker. As noted earlier in this chapter, olanzapine has many similarities to clozapine in its chemical structure as well as its receptor-blocking profile. Therefore, investigators have indicated that perhaps the multiple receptor–blocking properties of olanzapine are significant in its atypical antipsychotic effects. Blockade of dopamine receptors, 5-HT receptors, and histamine receptors, and perhaps other neurochemical properties as well, may be the result of the multiple receptor–blocking capabilities of the compound (Bymaster et al. 1999).

In clinical investigations with positron emission tomography (PET) imaging, Kapur et al. (1998) showed that olanzapine at a wide range of doses blocks a high percentage (95% or greater) of 5-HT_{2A} receptors and blocks dopamine receptors in a dose-dependent fashion—crossing the putative antipsychotic blockade line at doses commonly used to diminish psychotic symptoms of schizophrenia. This study indicated that olanzapine's primary mechanism was related to the blockade of dopamine receptors, and additionally noted that olanzapine showed stronger affinity for 5-HT_{2A} receptors than for dopamine receptors at all dosage ranges.

In addition to considering individual neurotransmitters, it has been noted that each neurotransmitter has multiple types of receptors. For dopamine, there are currently five different receptors that are grouped into two families (D_1 and D_5 vs. D_2, D_3, and D_4). Work by Casey (1993) with nonhuman primates found that there may be regionally specific characteristics of the atypical antipsychotic medications compared with the typical compounds. These regionally specific characteristics of receptors and the observation that antipsychotic medications such as olanzapine have regionally specific activity may explain the ability of atypical compounds to decrease psychotic symptoms without causing movement disorders (Stockton and Rasmussen 1996a). Such regional selectivity is supported by molecular biology studies, such as those by Robertson and Fibiger (1996), which have reported increases of c-fos expression, which is regionally specific for the caudate area of the brain.

A more compelling hypothesis regarding the atypicality of olanzapine has emerged from the in vivo PET scanning work being performed in a series of experiments at the University of Toronto and in Sweden. Results of the initial PET scanning studies of patients receiving clozapine indicated that there was atypical dopamine receptor binding (Farde and Nordstrom 1992; Farde et al. 1992; Kapur et al. 2000). The group subsequently found similar results for quetiapine and, to some degree, olanzapine (Kapur et al. 1998). The authors indicated that the successful reduction of psychotic symptoms in schizophrenic patients without movement disorder side effects may be the result of a "fast off" property of some of the atypical antipsychotic medications. They argued that for medicines that block the dopamine receptor but leave that receptor quickly, there may be an effect at the receptor to decrease psychosis but that a "physiological" dopamine activity at the receptor remains. Thus, for olanzapine, as likely also with clozapine and quetiapine, this may contribute to the treatment of schizophrenia while causing fewer EPS at standard doses. From a clinical view, it is important to note that at higher dosages of olanzapine (30 mg/day), higher dopamine receptor blockade is seen, and movement disorder side effects, such as akathisia, are more likely to occur.

In recent years, there has been substantial interest in the role of glutamate, an excitatory

neurotransmitter, in the pathophysiology of schizophrenia (see, e.g., Javitt and Zukin 1991; Krystal et al. 1994; Lahti et al. 1995). This theory is supported by the psychotomimetic properties of glutamate antagonists such as phencyclidine and ketamine. These NMDA receptor antagonists lead to a group of behaviors that often have closer parallels to schizophrenia than do those of the dopamine sympathomimetic agents, in both mice and humans. Clinical trial evidence points to the usefulness of glutamatergic agonists (e.g., D-cycloserine) in treating schizophrenia (Goff et al. 1995). People with schizophrenia have been shown to have decreased glutamine synthetase and glutamate dehydrogenase in the prefrontal cortex, thus impacting the glutamate-to-glutamine conversion (Burbaeva et al. 2003). A current strategy under investigation involves administration of compounds such as D-cycloserine to patients. When glutamatergic agents have been given to patients with schizophrenia, there has generally been a measurable improvement in cognition and a decrease in negative symptoms, unless clozapine (a glutamatergic partial agonist) is present (Evins et al. 2000). However, no measurable decrease in the positive symptoms of the illness has occurred. Thus far, glutamatergic agonists have shown mixed results, although further research on the NMDA receptor, as well as on glycine transport antagonists, is in progress (Javitt 2006). Recent studies have also shown that LY2140023, a metabotropic glutamate receptor agonist, may be effective in treating schizophrenia. In a Phase II trial comparing LY2140023 with olanzapine and placebo, LY2140023 produced improvement in positive and negative symptoms, as measured by the Positive and Negative Syndrome Scale (PANSS), and had rates of EPS and weight gain similar to those of placebo (Patil et al. 2007).

One way of examining the possible effect of olanzapine on glutamatergic measures was addressed in a study of rats with isolation-induced disruption of prepulse inhibition. Prepulse inhibition, a measure of sensory motor gating, is believed to be abnormal in patients with schizophrenia. In a study by Bakshi et al. (1998), both quetiapine and olanzapine reversed the isolation-induced prepulse inhibition deficit. Because there is a connection between NMDA antagonists and prepulse inhibition, this finding is evidence of olanzapine's effect on the glutamatergic system. Glutamine synthetase–like proteins (GSLP) and glutamate dehydrogenase have also been seen to be significantly higher in schizophrenia patients. Burbaeva et al. (2006) have shown that patients with a higher amount of GSLP in the platelets tend to respond more quickly to medication and specifically that olanzapine treatment alters the amounts of these peptides, further enhancing its antipsychotic properties.

Utilizing magnetic resonance spectroscopy (MRS), Goff et al. (2002) have shown a more direct measure of olanzapine on patients' glutamate levels. They found that after a switch from conventional antipsychotic medications to olanzapine, serum glutamate levels increased appreciably. Brain glutamate levels, however, did not increase. Further examination indicated that in the patients whose negative symptoms improved, brain glutamate concentrations increased.

The neuropeptide neurotensin also has been explored for its role in the pathophysiology of schizophrenia (Nemeroff et al. 1983), with several findings supporting an association of neurotensin with the symptoms of schizophrenia. Such findings include the close anatomical association between neurotensin and other neurotransmitter systems that have been implicated in schizophrenia, changes in neurotensin brain levels in animals when antipsychotic medications have been administered, and similarities between the effects of centrally administered neurotensin and the effects of antipsychotic medications. The effect of olanzapine and other antipsychotics on the neurotensin system has been investigated by using molecular biology techniques. After assessing neurotensin messenger RNA (mRNA) in the rat brain, the investigators reported increases in neurotensin mRNA when olanzapine was administered. The pattern of neurotensin changes seen with olanzapine was different from the pattern seen with haloperidol. These results are more similar to the results seen with the antipsychotic medication clozapine and show the effect of olanzapine on another system with importance in schizophrenia (Binder et al. 2001; Radke et al. 1998).

In summary, regarding the mechanism of action of olanzapine, a second-generation antipsychotic with well-demonstrated efficacy for psychosis in patients with schizophrenia, research indicates an effect on dopamine, acetylcholine, histamine, 5-HT (with greater affinity for 5-HT receptors than for dopamine receptors). glutamate, and neurotensin. Other effects are in the process of being evaluated. These effects have been measured by both biochemical assay and MRS and have been demonstrated in both human and animal models of the illness. At this time, dopamine receptor–blocking capabilities appear to be a necessary but not sufficient characteristic of an antipsychotic medication. The other studied mechanisms, when taken in total, may be the factors leading to olanzapine's broad efficacy and side-effect profile.

INDICATIONS AND EFFICACY

To be prescribed in the United States, a medication must be approved by the FDA for a specific indication. This initial approval is based on an assessment of efficacy and safety requiring multiple tests of a medication compared with placebo and at least two studies demonstrating efficacy compared with placebo. In the case of olanzapine, its original indication was for psychosis. Currently, it has multiple indications, including schizophrenia, acute mania or mixed states in bipolar disorder, and as monotherapy or combination therapy in the maintenance treatment of bipolar disorder. The olanzapine–fluoxetine combination (OFC) has an FDA indication for bipolar depression. Intramuscular olanzapine carries an indication for acute agitation in schizophrenia and bipolar mania. Once a medication has received an FDA indication, physicians are able to use that medication off label for other theorized indications. Olanzapine has been studied, and at times used with limited evidence, in several other illnesses. In this section, we present the evidence base that supports the use of olanzapine for its FDA-indicated usages as well as for other off-label usages.

Schizophrenia

As noted earlier, olanzapine was originally developed as a medication with potential for treating schizophrenia, mania, and anxiety. During the 1990s, significant energy was focused on the development of antipsychotic medications with new actions such that patients could have a reduction of psychosis with fewer side effects, especially neurological side effects. To gain FDA approval for the treatment of schizophrenia, olanzapine was tested in four pivotal studies to assess the compound for efficacy, safety, and dose ranging. The earliest testing of olanzapine was an assessment of olanzapine in doses of 5–30 mg following an initial starting dose of 10 mg. Brief Psychiatric Rating Scale (BPRS) scores were reduced substantially for the participants in the study, and EPS were low (Baldwin and Montgomery 1995). These encouraging results led to further studies and pointed to a dose range to be tested.

Efficacy Studies

The first pivotal study examined a dose of 10 mg of olanzapine. The study showed that 10 mg of olanzapine was statistically significantly superior to placebo on objective rating scales (Beasley et al. 1996a). The next step was a dose-ranging study of olanzapine compared with haloperidol and placebo. The dosage ranges were 1) low (5±2.5 mg/day), 2) medium (10±2.5 mg/day), and 3) high (15±2.5 mg/day). Haloperidol was dosed to 15±2.5 mg/day. The medium and high doses of olanzapine and haloperidol led to significant improvements compared with placebo (Beasley et al. 1996b). Tollefson and Sanger (1997), after analysis of these early data, pointed out that the effect on negative symptoms by olanzapine was independent of movement disorders.

Another large international multicenter trial used a flexible dosing strategy to show a statistical superiority of olanzapine over haloperidol. In this study, patients were started on olanzapine or haloperidol at dosages ranging from 5 to 20 mg/day. Ultimately, patients received olanzapine 13 mg/day compared with haloperidol 11.8 mg/day (Tollefson et al. 1997).

The third pivotal study included an interesting arm—olanzapine 1 mg/day—in comparison to low-, medium-, and high-dose olanzapine and haloperidol (15±5 mg/day). This study established the statistical efficacy of low- and high-dose olanzapine compared with 1 mg/day of olanzapine (Beasley et al. 1997).

The group of studies described above led to the approval of olanzapine for psychosis (later changed to schizophrenia). Several other studies have reinforced olanzapine's efficacy for the treatment of schizophrenia. Coupled with its efficacy and substantially fewer movement disorder side effects, olanzapine has become an important addition to the armamentarium of the psychiatrist treating schizophrenia. Leucht et al. (1999) reported that olanzapine was statistically more effective than placebo (moderate effect) and also more effective than haloperidol (small effect) on global schizophrenia symptomatology.

Olanzapine has shown superiority to haloperidol in several comparison studies. In a double-blind, placebo-controlled trial, it was shown to be modestly superior to haloperidol in improving cognitive functioning (Purdon et al. 2000). Its superiority was again demonstrated in a study of patients with prominent negative symptoms. Followed for 1 year, the olanzapine group and the risperidone group performed modestly better than the haloperidol group (Gurpegui et al. 2007). In a randomized, controlled trial versus haloperidol, 31.3% of olanzapine-treated patients showed an improvement in cognitive symptoms at study endpoint, compared with 12.5% for the haloperidol group (Lindenmayer et al. 2007). Despite these findings, other studies have shown no difference between olanzapine and haloperidol in effects on cognitive symptoms in schizophrenia patients with treatment-resistant illness (Buchanan et al. 2005).

A large National Institute of Mental Health (NIMH)–funded trial was recently completed that sought to compare the atypical antipsychotics olanzapine, risperidone, quetiapine, and ziprasidone with perphenazine in order to understand the efficacy and side-effect profiles of the newer versus older antipsychotic medications (Lieberman et al. 2005). The study, Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE), was designed to provide a double-blind yet reasonably naturalistic way for clinicians to treat patients, using the time to discontinuation as a primary outcome variable. This outcome was intended to provide an estimate of overall efficacy and morbidity on a particular medication, as it was considered likely that patients would discontinue the medication if it was not working for any particular reason. Although the study design and its findings have at times been controversial, olanzapine demonstrated the longest time to discontinuation in the trial, based on all-cause discontinuation. Olanzapine had the highest rate of discontinuation due to metabolic complications such as weight gain, while perphenazine had the highest rate of discontinuation for EPS. Overall, however, the discontinuation rate was high for all medications, with nearly 75% of patients changing medications within the 18-month study duration. Much has been written since the initial findings were published, including analyses of cost-effectiveness (Rosenheck et al. 2006), psychosocial functioning (Swartz et al. 2007), and switching of medications (Essock et al. 2006), as well as numerous editorials about the treatment implications from the study and about the methodology of the study design.

The pharmacoeconomics of using olanzapine in the treatment of schizophrenia are complicated. Rosenheck et al. (2003) have demonstrated that in pharmacoeconomic studies, olanzapine and haloperidol differentiate from each other. In these studies, haloperidol is accompanied by prophylactic benztropine to ward off EPS. When the cost-effectiveness of olanzapine and the other atypical antipsychotics was evaluated in the CATIE, perphenazine came out as the most cost-effective of the medications studied (Rosenheck et al. 2006). The general equality of efficacy among the medications, at least with respect to rehospitalization rates, as well as the decreased cost for the older medication, is partially responsible for this difference. Additionally, the metabolic consequences of olanzapine treatment become significant when one considers the overall total cost for the medication within the

entire health care system, as the increased rates of diabetes and associated medical conditions can cost thousands of dollars per year in associated medication, hospitalization, medical tests, and lost productivity. However, because the older antipsychotics carry a higher risk of neurological side effects, adherence to medications becomes relevant, and maintenance on medication is crucial to preventing relapse and expensive hospitalizations.

Schizophrenia is not always responsive to traditional antipsychotic medication treatment. Clozapine was shown to be superior to chlorpromazine in treating schizophrenia that is refractory to other medications, and this led to its approval for traditional antipsychotic medication failures (Kane et al. 1988). However, clozapine has a unique and potentially more dangerous side-effect profile, with a rigorous associated treatment regimen, which can make it a difficult medication to use. Assessment of olanzapine for this difficult-to-treat patient group did not indicate usefulness for the treatment-refractory group in a stringent nonresponder protocol (Conley et al. 1998). However, in an Eli Lilly–sponsored double-blind, noninferiority multicenter trial, olanzapine was shown to lower PANSS scores similarly to clozapine, although superiority of one agent over another was not addressed in this study design (Tollefson et al. 2001). A second phase of the CATIE examined the use of clozapine in patients with treatment-refractory illness and found that clozapine was a superior treatment for patients in which failure with other atypical medications had occurred, based on the time to discontinuation (McEvoy et al. 2006).

Olanzapine has often been linked to improvements in the negative symptoms and cognitive symptoms of schizophrenia, although perhaps with less potency than for the positive symptoms. Negative and cognitive symptoms often do not respond to conventional antipsychotics and have even been shown to worsen, particularly if an adjunctive anticholinergic medication is used for treatment of EPS. The efficacy of olanzapine for negative symptoms was first reported by Tollefson et al. (1997), following completion of a large double-blind trial of olanzapine and haloperidol. A factor analytic model was used to determine the effect of olanzapine on negative symptoms, separate from the effect on positive symptoms. When all symptom improvements were taken into consideration, olanzapine-treated subjects had greater improvement in negative symptoms on both the Scale for the Assessment of Negative Symptoms (SANS) and the BPRS negative symptom subscore. In a flexible-dose comparison between risperidone and olanzapine in patients followed for 1 year, olanzapine-treated patients showed significantly greater improvement on SANS scores than did risperidone-treated patients (Alvarez et al. 2006). Interestingly, in a study by researchers from Eli Lilly that followed patients taking either quetiapine or olanzapine for 6 months, the two groups showed similar improvements on the SANS at study completion (Kinon et al. 2006). In a study comparing olanzapine and amisulpride, there was also no difference between the two medications, and only low-dose olanzapine outperformed placebo, with higher-dose olanzapine (20 mg) and amisulpride (150 mg) not showing a statistical benefit on the SANS (Lecrubier et al. 2006).

Cognitive functioning is the most important prognostic indicator for schizophrenia (Green 2006). In a 1-year comparison of olanzapine with risperidone, both groups showed modest benefits on a cognitive function battery (Gurpegui et al. 2007). In a study conducted over a 1-year period by Eli Lilly researchers in Spain, olanzapine showed greater benefit on social functioning than did risperidone, as assessed by scores on the Social Functioning Scale (SFS). The greatest difference was in occupation/employment, but improvements were also seen in measures of independence, social engagement, and recreation (Ciudad et al. 2006).

Olanzapine is indicated for the treatment of schizophrenia; however, studies leading to FDA approval are designed to include only patients between the ages of 18 and 65 years. Therefore, usefulness of olanzapine for young people with schizophrenia and patients older than 65 years was not addressed in the early studies. In a recent systematic review of the literature in children, second-generation antipsychotics were shown to be beneficial overall for targeting psychotic symptoms, although there

is still a need for research on the long-term safety profile of these agents (Jensen et al. 2007). To inform clinicians about the use of olanzapine in adolescents with schizophrenia, Findling et al. (2003) performed an open-label study of olanzapine using outcome measures from the PANSS and Clinical Global Impressions (CGI) Scale. In the 16 adolescent patients studied, there was a statistically significant reduction in PANSS-rated symptoms, and further exploration of the PANSS subscales found an effect on positive, negative, and general symptoms. The patients ended the study receiving an average olanzapine dosage of 12.4 mg/day, which was similar to the dosage used in many adult schizophrenic patients. A double-blind, flexible-dose study conducted in North Carolina demonstrated similar efficacy for risperidone, olanzapine, and haloperidol in psychotic young people (Sikich et al. 2004). In an NIMH-sponsored trial of adolescents with treatment-refractory schizophrenia, clozapine and olanzapine were compared. While clozapine showed a modestly more consistent pattern of symptom alleviation, particularly for negative symptoms, more side effects were noted in the clozapine group (Shaw et al. 2006).

The use of olanzapine in a population considered to be at risk for schizophrenia but not yet meeting full symptom criteria was evaluated in a double-blind multicenter study. The olanzapine group demonstrated a decreased rate of conversion to psychosis compared with the placebo group, although the difference did not quite reach statistical significance. However, a number of factors, including high dropout rates in both groups, lack of a systematic method for diagnosing Axis I disorders, and the method of patient selection, limited the generalizability and reliability of the findings (McGlashan et al. 2006). The number needed to treat, a measure of effect size, was 4.5 in this study; thus, early medication treatment may benefit some patients. Nonetheless, given the long-term side-effect consequences of antipsychotics, much further refinement, including greater precision in identifying appropriate candidates for treatment, is required before presyndromal medication therapy can be considered to be evidence based.

At the other end of the age spectrum, olanzapine has been tested in the treatment of several syndromes in the elderly. Further discussion of the use of olanzapine in dementia will follow in a separate subsection. Special challenges are involved in treating any disorder in elderly individuals, and schizophrenia or other psychosis is no exception. An early presentation of data reported a comparison of olanzapine with haloperidol in elderly psychotic patients. This report noted a decrease in symptoms for the olanzapine-treated patients, but the reduction was not statistically greater than in the haloperidol-treated patients. Notably, more movement disorder side effects were seen in the haloperidol group (Reams et al. 1998). The movement disorder results are important for the elderly, because they are at high risk for tardive dyskinesia. A more recent study of a group of older patients with chronic schizophrenia actually showed a statistical advantage for olanzapine (Barak et al. 2002). For a broad group of psychotic patients, Hwang et al. (2003) reported reduction in BPRS symptoms in 94 acutely ill patients, some with organic psychosis, thus illustrating the usefulness of olanzapine in this older patient group. As in any treatment with the elderly, special care must be taken for cardiovascular complications. With olanzapine, orthostatic hypotension, oversedation, and thus the risk of falls must be factored into the dosing decision (Gareri et al. 2006).

Treatment Approaches

Early studies of olanzapine assessed dosages ranging from 5 to 30 mg/day. When olanzapine was initially released, it was recommended that it be started at a dosage of 10 mg/day—frequently as a bedtime dose. Subsequently, clinicians have used average dosages higher than 10 mg/day (e.g., approximately 13 mg/day). In the CATIE, the average daily dose in the flexible-dose segment (available doses were 7.5, 15.0, 22.5, and 30.0 mg) was 20.1 mg (Lieberman et al. 2005). For inpatient use, clinicians often will give patients 5 mg of olanzapine in the morning and 10 mg at bedtime (Schulz 1999). Some patients appear to have an inadequate response to olanzapine at the recommended doses, so clinicians have assessed the usefulness of olanzapine at dosages above the

recommended 20 mg/day. Many inpatient clinicians employ a loading strategy with olanzapine, particularly in patients presenting with agitation, using up to 40 mg/day for the first 2 days and gradually decreasing the dose to a goal of 20–30 mg/day (Baker et al. 2003; Brooks et al. 2008). While sedation and hypotension must be watched for in any individual patient, increased rates of those side effects were not seen in a study comparing the loading dose strategy with conventional 10-mg/day dosing (Baker et al. 2003).

Typically, agitated patients are best treated with the rapid-dissolving preparation of olanzapine. Given their faster onset of action compared with the conventional pill form and their decreased risk for "cheeking" of the medication, rapid-dissolving tablets are preferable in the acute setting, particularly when some sedation is also needed. When patients are severely agitated, use of injectable olanzapine is often necessary. The intramuscular preparation also has a rapid onset of action, similar to that of dissolvable tablets, and a certainty of delivery that is imperative in an acute emergency. The injectable preparation has been shown to be superior to placebo at doses of 10 mg and as effective as haloperidol, with significantly fewer side effects (Breier et al. 2002). Case reports, however, caution against use of olanzapine in conjunction with intramuscular lorazepam because of hypotension (Zacher and Roche-Desilets 2005).

Empirical studies of a "lowest effective dose" of olanzapine for long-term maintenance have not been performed, so clinical judgment regarding dose is needed at all stages of treatment. For schizophrenia, combinations of medications are sometimes helpful. As can be seen throughout this chapter, olanzapine has been tested in combination with antidepressant and mood-stabilizing compounds in patients with mood disorders. Therefore, these combinations in schizophrenic patients appear safe and appropriate when used judiciously.

Bipolar Disorder and Major Depressive Disorder

In the past, before the introduction of atypical antipsychotic medications, it was well known that traditional antipsychotic medications were useful in the treatment of mania. Medications such as chlorpromazine and haloperidol could rapidly reduce agitation and excitement as well as diminish the psychotic symptoms of mania, when present. Early studies with clozapine indicated that this atypical agent was even useful in reducing symptoms of bipolar disorder refractory to previous mood stabilizer and traditional antipsychotic medication treatment (Calabrese et al. 1996). An assessment of the effect of olanzapine on symptoms of schizoaffective disorder provided a rationale for studying olanzapine in bipolar patients. The schizoaffective patients were identified as part of a larger study. When the results for the schizoaffective disorder patients were analyzed, those patients who received olanzapine had a superior outcome, compared with patients who received haloperidol, on many, but not all, measures (Tran et al. 1999).

Therefore, a series of studies was conducted to assess the efficacy and safety of olanzapine in the treatment of bipolar disorder. The first controlled study was a comparison of olanzapine with placebo in a 21-day study that used objective rating scales (Tohen et al. 1999). The dosage of olanzapine could be adjusted between 5 and 20 mg/day. An analysis of the Young Mania Rating Scale (YMRS) showed a significant score reduction for patients taking olanzapine compared with those taking placebo. Of interest in treating bipolar patients, no difference was seen in the outcomes for depression; therefore, olanzapine did not lead to depression. It is also well known that bipolar patients are sensitive to the potential of movement disorders from antipsychotic medications. In this study, EPS were not more frequent in the olanzapine-treated patients than in the patients taking placebo (Tohen et al. 1999). These findings were confirmed by a second pivotal study showing an advantage of olanzapine over placebo (Tohen et al. 2000). An open-label follow-up (49 weeks) added valuable information, especially noting that decreases in YMRS scores continued. For the longer term, depression scores also improved. Importantly, for the patients who were exposed to olanzapine at a mean dosage of approximately 14 mg/day, no cases of tardive dyskinesia occurred (Sanger et al.

2001).

An important question of practical interest is how olanzapine compares with conventional mood stabilizers such as lithium or valproic acid. The first study to approach this question, which was a small pilot study (*N* = 30 patients), compared olanzapine with lithium. No difference was found between BPRS and Mania Scale scores; patients in both groups showed significant improvement (Berk et al. 1999).

In a larger double-blind trial conducted by Eli Lilly, olanzapine was compared with lithium in the maintenance treatment of bipolar disorder (mixed or manic) (Tohen et al. 2005). In the study, patients were stabilized on a combination of lithium and olanzapine and then randomly assigned to receive one or the other for 52 weeks. In the noninferiority analysis, olanzapine was shown to prevent depression relapse as well as lithium, and in fact it had a lower rate of mixed or manic relapse over the 52-week follow-up. Weight gain was higher in the olanzapine group (Tohen et al. 2005).

Further studies confirmed the equivalent efficacy of olanzapine and the most widely used anticonvulsant mood stabilizer, divalproex (Tohen et al. 2002). In this 3-week study, olanzapine was found to be superior to placebo in reducing mania ratings (YMRS). More recently, another comparison of the two compounds confirmed no differences in treatment outcome but did note more sedation and weight gain in the olanzapine group (Zajecka et al. 2002). The group of studies focusing on olanzapine's use in treating mania that showed reduction of manic as well as psychotic symptoms led to the approval of olanzapine by the FDA for the treatment of manic symptoms. Mean dosages of olanzapine used in monotherapy appear similar to those used in schizophrenia: 13 mg/day. For acute mania, a recent study has shown the usefulness of intramuscular olanzapine in treating agitated bipolar patients (Meehan et al. 2001).

Olanzapine has also been shown in several studies to be an effective adjunctive agent. In another study conducted by the group at Eli Lilly, olanzapine was found to reduce suicidal ideation in bipolar patients when added to a regimen that included lithium or valproic acid (Houston et al. 2006).

The treatment of bipolar depression is often complicated. Monotherapy with antidepressants is associated with an increased risk of switching into mania. Olanzapine packaged with fluoxetine—the olanzapine–fluoxetine combination (OFC)—has been studied in the treatment of depression in bipolar disorder. In an 8-week double-blind trial conducted by Eli Lilly, OFC was compared against olanzapine monotherapy and placebo in patients with bipolar I disorder in a depressed phase. While both treatments were more effective than placebo, OFC was significantly more effective than either olanzapine or placebo in treating depressive symptoms. OFC-treated patients showed greater improvement in mood compared with olanzapine-treated patients by the fourth week of the study (Tohen et al. 2003). Benefits were also seen in the subjects' health-related quality of life (Shi et al. 2004). OFC was also recently compared with lamotrigine in a 7-week study (Brown et al. 2006). Although OFC demonstrated a statistical separation from lamotrigine by the first week, it is difficult to make a full comparison in such a short study. As lamotrigine requires slow titration to decrease the risk of serious rash, it was received at the target dose (200 mg/day) only for the last 2 weeks of the study, whereas the OFC dosage could be titrated to therapeutic levels much more quickly. Although the rapid titration of OFC is helpful when a more urgent approach is required, further study is needed to determine whether OFC's greater benefits persist once lamotrigine has had an opportunity to remain at a therapeutic dose for a longer period of time (Brown et al. 2006). Rates of treatment-emergent mania with OFC were low and did not significantly differ from rates with placebo or olanzapine monotherapy (Amsterdam and Shults 2005; Tohen et al. 2003).

Patients with schizophrenia frequently have symptoms of depression, whereas others may appear to be depressed secondary to negative symptoms and the use of typical antipsychotic medications (Siris et al. 2000). This serious problem was addressed by Tollefson et al. (1998a, 1998b), who examined

the results of olanzapine pivotal trials in order to assess the effect of olanzapine on symptoms of depression in schizophrenic patients. In the Tollefson et al. (1998b) study, they used a path analysis to control for negative symptoms and EPS. They found a statistically significantly greater effect of olanzapine on depression compared with placebo, and at medium (102.5 mg/day) and high dosages, reductions in BPRS Anxiety/Depression scale scores were similar to those seen with haloperidol. For subjects with higher depression scores, olanzapine was statistically superior to haloperidol. These results demonstrate that olanzapine may have a useful effect in this patient group and suggest that further exploration of the potential for olanzapine in treating depressive mood disorders is warranted.

The tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), and serotonin–norepinephrine reuptake inhibitors (SNRIs) are all effective treatments for depression compared with placebo, but not all patients' symptoms respond to these agents. These patients with treatment-refractory illness present a substantial challenge to clinicians and investigators alike. Augmentation strategies, including lithium, liothyronine, and other medications, have been tried with limited success and risks of side effects. OFC has been studied in treatment-refractory major depressive disorder. Thase et al. (2007) conducted a study comparing OFC against olanzapine or fluoxetine monotherapy in patients who had failed to respond to at least two prior trials with antidepressants. In the pooled analysis, which separated the subjects into two groups (group 1 had failed previous treatment with an SSRI; group 2 had failed previous treatment with an agent other than an SSRI), OFC showed improvement over olanzapine or fluoxetine monotherapy on the Montgomery-Åsberg Depression Rating Scale (MADRS). Although the difference was not significant for group 1 alone, it was significant for group 2 (Thase et al. 2007). In a double-blinded trial sponsored by Eli Lilly that compared olanzapine, fluoxetine, OFC, and venlafaxine, all treatments showed similar rates of efficacy (Corya et al. 2006).

Another significant challenge in treating mood disorders is developing a strategy for patients who have major depression with psychotic features. Earlier work by Spiker et al. (1985) had indicated greater efficacy for a combination of antipsychotics and antidepressants over each administered alone. Because olanzapine has low levels of EPS compared with typical antipsychotics and has a positive effect on mood in schizophrenic patients (Tollefson et al. 1998a, 1998b), it would be a good candidate for depression with psychosis. In an open-label study, olanzapine monotherapy produced a significant reduction in symptoms of both depression and psychosis (measured by the Scale for the Assessment of Positive Symptoms). Again, it must be pointed out that this was an early pilot study, and no comparisons with other treatments were made (for an update on the overall significance of and approach to major depression with psychotic features, see Schatzberg 2003).

In summary, the newer atypical antipsychotic medications have found a role in treating not only mania but also depression. Olanzapine has demonstrated efficacy in both acute and maintenance phases of bipolar disorder, and when combined in the OFC formulation has shown benefit in treating depression in bipolar I disorder. Particularly in cases where psychosis is prominent with mania, olanzapine is a reasonable first-line agent, although consideration must be given to the potential metabolic consequences. In depression, olanzapine has been studied primarily in treatment-refractory cases, and given its metabolic side-effect profile, it is most appropriate for use in such cases.

Dementia-Related Agitation and Psychosis

Olanzapine is often used in an off-label manner for the treatment of dementia. Alzheimer's disease, the most prevalent form of dementia in the Western world, is characterized by progressive memory loss, decreased executive functioning, and deficits in language and visuospatial skills. However, Alzheimer's disease is also frequently accompanied by psychotic and mood symptoms, such as depression, paranoia, and hallucinations. In Lewy body dementia, visual hallucinations are a common manifestation, along with parkinsonism and autonomic instability. Frontotemporal dementia is characterized by disinhibition and euphoria, along with memory loss and changes in motor function

(Bird and Miller 2005). Olanzapine and other antipsychotic medications are typically used off-label for treatment of the neuropsychiatric manifestations of dementia. As elderly people are generally more sensitive to the EPS and tardive dyskinesia associated with first-generation antipsychotic medications, the second-generation medications are often preferred when antipsychotics are needed.

A large placebo-controlled trial of olanzapine in Alzheimer's patients showed that the lower dosages of olanzapine (5–10 mg/day) were significantly better than placebo in treating target symptoms of agitation, hallucinations, and delusions (Street et al. 2000, 2001). However, the treatment of dementia-related psychosis is complicated. The FDA recently mandated placement of a black box warning on the prescribing information of antipsychotic medications calling attention to the increased risk of death, primarily from cardiovascular and infectious complications. According to the warning, second-generation antipsychotic use over a 10-week period carries a 1.6- to 1.7-fold increased risk of mortality based on data from 17 placebo-controlled trials of atypical antipsychotics in dementia-related psychosis. The warning does not differentiate medications and has subsequently been extended to apply to first-generation antipsychotics as well. In a recent Cochrane review of atypical antipsychotic use in agitation associated with dementia, both risperidone and olanzapine were shown to effectively treat the agitation but were associated with an increased risk of stroke, even at olanzapine doses of less than 10 mg/day (Ballard and Waite 2006). However, the finding of increased stroke risk with antipsychotics, and the necessity of the black box warning, remains controversial, as several large population-based studies have reported conflicting results (Gill et al. 2005; Herrmann and Lanctot 2005; Herrmann et al. 2004; Layton et al. 2005; Schneider et al. 2006a). Ultimately, clinical judgment and thorough documentation are important, as in certain situations the hazards of untreated psychotic agitation may outweigh the potential risks of treatment.

Several studies have examined olanzapine in the treatment of dementia without agitation (Brooks and Hoblyn 2007). A placebo-controlled multicenter trial conducted by researchers at Eli Lilly evaluated olanzapine at low fixed doses (1.0, 2.5, 5.0, and 7.5 mg/day) in the treatment of dementia-related psychosis (De Deyn et al. 2004). Although olanzapine did not separate from placebo on the primary outcome measure, Hallucinations and Delusions of the Neuropsychiatric Inventory—Nursing Home edition (NPI/NH), improvements were seen in each of the dosage groups studied. All patients who received dosages of 2.5 mg/day or greater were initially started on 2.5 mg/day, with the dosage titrated upward by 2.5 mg/week (as indicated based on their assigned study group), and there was an overall difference from placebo in the acute phase of the study, suggesting that a 2.5-mg dose was an effective starting dose in the more acute setting. On some secondary outcome measures, the greatest improvement was seen with the highest olanzapine dosage (7.5 mg/day), suggesting that for some patients, an increase to 7.5 mg/day is beneficial. Because no higher dosages were used in the study, it is unclear whether continuing to increase the dosage would lead to greater efficacy (De Deyn et al. 2004).

In treatment of cognitive decline, acetylcholine has been the focus of treatments aimed at protecting people with dementia from undergoing as rapid a deterioration as they would naturally. Cholinesterase inhibitors have been used on that basis. Olanzapine may have beneficial effects on prefrontal cortex cholinergic and serotonergic neurons that may facilitate acetylcholine release to that region. However, in a double-blind study conducted by researchers at Eli Lilly, olanzapine was shown to worsen cognitive functioning, as assessed on the Alzheimer's Disease Assessment Scale for Cognition (ADAS-Cog), and there was no statistical difference between the olanzapine and placebo groups in scores on the Clinician's Interview-Based Impression of Change (CIBIC) scale (Kennedy et al. 2005). Patients in the olanzapine group also showed worsening on the Mini-Mental State Examination (MMSE). Previous studies have found little to no benefit on cognition from olanzapine treatment in nonagitated patients with dementia (De Deyn et al. 2004; Street et al. 2000).

The CATIE studies described earlier also had an Alzheimer's disease component in which olanzapine,

risperidone, and quetiapine were compared with placebo for the treatment of psychosis and agitation in outpatients (Schneider et al. 2006b). Patients were included if they had psychotic symptoms and lived either in an assisted living facility or at home, but were excluded for skilled nursing needs or primary psychotic disorders. Patients who were to receive cholinesterase inhibitors or antidepressants were also excluded from the study. Like the schizophrenia portion of CATIE, the primary outcome variable was time to discontinuation. No difference was found among the groups in time to discontinuation, and no benefit was seen on the Clinical Global Impressions of Change (CGI-C). The average time to discontinuation ranged between 5 and 8 weeks among the treatments. Discontinuation because of lack of efficacy occurred sooner for placebo or quetiapine than for risperidone or olanzapine. Side effects such as parkinsonism, sedation, and higher body mass index were all increased with the study medications over placebo (Schneider et al. 2006b).

Overall, there are limited data to support the effectiveness of atypical antipsychotics in the treatment of dementia. Risks for worsened cognitive function and metabolic concerns must be considered when use of antipsychotic medications is contemplated. Nonetheless, there are times when behavioral consequences and patient safety require more aggressive treatment, and antipsychotic medication may be warranted. Ultimately, a painstaking evaluation of the risk–benefit ratio of antipsychotic medications must precede any decision to prescribe these agents, in both the acute and the long-term time frames. Further study is needed, however, regarding the use of second-generation antipsychotic medications in this population (Schneider et al. 2006a).

Borderline Personality Disorder

Borderline personality disorder is a severe psychiatric illness that afflicts nearly 1% of the population (Torgersen et al. 2001). It is well known to clinicians that symptoms of affective lability, self-injurious behavior, and impulse/aggression action patterns make this patient group difficult to treat. Patients with borderline personality disorder are often taking several medications of various classes, including mood stabilizers, antidepressants, and antipsychotics. Based on earlier studies indicating that low doses of traditional antipsychotic medications may be useful for borderline personality disorder (Goldberg et al. 1986; Soloff et al. 1986), Schulz et al. (1999) reported on an open-label study that found that olanzapine led to a substantial decrease in Symptom Checklist–90 symptoms, as well as on objective measures of impulsivity and aggression. Of the patients entered in the trial, 9 of 11 (82%) completed the study. The design of the trial allowed for early flexible dosing, and the subjects ended the 8-week trial taking olanzapine at an average dosage of approximately 7.5 mg/day, usually at bedtime. Zanarini and Frankenburg (2001) extended this open-label trial and showed superiority of olanzapine over placebo in a longer-term (26-week) study. This interesting study of only women indicated that lower dosages (5 mg/day) of olanzapine can be useful and are associated with only minimal weight gain.

In a study comparing olanzapine, fluoxetine, and OFC in women with borderline personality disorder, olanzapine monotherapy was found to be more effective in treating the depressive symptoms of borderline personality disorder than either fluoxetine or OFC, as assessed on the MADRS. Additionally, olanzapine was superior to fluoxetine in treating symptoms of impulsivity and aggression, as measured by the Overt Aggression Scale (OAS). Weight gain was seen in a greater percentage of olanzapine-treated patients than of fluoxetine-treated patients (Zanarini et al. 2004).

Dialectical behavioral therapy (DBT) is a mainstay of current treatment for borderline personality disorder. In a double-blind, placebo-controlled trial, olanzapine was studied as an adjunctive agent in patients receiving DBT. Impulsive and aggressive behaviors were found to be lower in the group that received olanzapine than in the placebo group. The average olanzapine dosage in the trial was 8.8 mg/day. Statistically significant levels of weight gain and dyslipidemia were observed in the olanzapine group compared with the placebo group (Soler et al. 2005). Therefore, with consideration for side effects, olanzapine may be helpful for a broader range of illnesses, particularly when used in

conjunction with psychotherapy.

Anorexia Nervosa

Anorexia nervosa is a common and severe psychiatric illness that may well have the highest mortality of all mental disorders. Among the symptoms of this illness is severe restriction of food intake, leading to low weight; however, patients also have psychotic-like levels of self-perception of body size and appearance and unusual ideas about food and metabolism. Some investigators have begun to explore the possibility that olanzapine may help with this patient group. Initially, reports were largely from pilot studies, including case series, but data are now emerging from small controlled trials.

In an open-label trial, 17 patients hospitalized for anorexia nervosa were given olanzapine in conjunction with concurrent cognitive-behavioral therapy (CBT) and DBT group treatment (Barbarich et al. 2004). Olanzapine was initiated at a dosage of 1.25–5.00 mg/day, with upward titration as needed, balancing sedation and side effects with efficacy. Although patients showed improvement in weight as well as in Beck Depression Inventory (BDI) and Spielberger State-Trait Anxiety Inventory (STAI) scores, the lack of a control group limits the validity of these results (Barbarich et al. 2004).

Because olanzapine has weight gain as a significant side effect, the utility of that effect and the mechanism behind it have become a target for research. Ghrelin and leptin are hormones associated with satiety. In a double-blind, placebo-controlled trial, olanzapine was given concurrently with CBT in patients with anorexia, and ghrelin and leptin levels were assessed over 3 months. While both the olanzapine patients and the placebo patients gained weight, there was no statistical difference between groups in the amount of weight gained, nor in leptin or ghrelin levels, which remained unchanged over the course of the study (Brambilla et al. 2007).

In addition to severe distortions of body image, people with anorexia nervosa often have ruminations and obsessions about their bodies and food intake that can lead to significant distress as well as morbidity and mortality in the illness. In a pilot study in Australia, olanzapine was compared with chlorpromazine in a flexible-dose trial. Based on assessments with self-report instruments, olanzapine demonstrated a benefit for the obsessive ruminations seen in anorexia (Mondraty et al. 2005).

As the newer second-generation antipsychotic olanzapine continues to be tried in illnesses beyond psychosis, its potential benefit in anorexia will be followed up closely. Even though olanzapine has the side effects noted in other sections of this chapter, this illness is of such severity that further investigation of a possible role for olanzapine in its treatment is warranted.

Obsessive-Compulsive Disorder

Obsessive-compulsive disorder (OCD) is characterized by repetitive thoughts and behaviors that are often disabling and are difficult to treat. Affecting up to 2%–3% of the population, OCD has a very high prevalence and is the fourth most common psychiatric condition. Because nearly half of patients do not respond to conventional treatments with SSRIs, augmentation strategies are often sought. A significant portion of patients with OCD have comorbid psychosis. Second-generation antipsychotics had a number needed to treat of 4.5 to achieve a 35% reduction in Yale-Brown Obsessive Compulsive Scale (Y-BOCS) score, according to a systematic review (Bloch et al. 2006). Olanzapine was first evaluated as an adjunctive agent in several open-label trials and case series (Bogetto et al. 2000; D'Amico et al. 2003; Francobandiera 2001; Koran et al. 2000). In a small double-blind, placebo-controlled augmentation study (Bystritsky et al. 2004) in patients who had failed to respond to conventional treatment with serotonin reuptake inhibitors, the olanzapine-augmentation group showed a statistically significant decrease of 4 points on the Y-BOCS compared with the placebo group, which showed a slight gain in Y-BOCS score over the 6-week study duration. Subjects could be on any serotonin reuptake inhibitor, and the dosing of olanzapine was flexible (average dosage = 11 mg/day). In another double-blind, placebo-controlled augmentation trial, patients who were taking

fluoxetine 40 mg, generally considered a low dose for treatment of OCD, were randomly assigned to augmentation with either olanzapine (up to 10 mg/day) or placebo and followed for 6 weeks. In this study, there was no statistical difference between the groups; however, that could be attributed to the relatively low dose of fluoxetine used in the study and the high rate of response in the placebo group (Shapira et al. 2004). In an open-label study, subjects received olanzapine augmentation in addition to a serotonergic reuptake inhibitor and were followed for 1 year. Those who evidenced benefit at 12 weeks tended to continue to show a benefit when assessed at 1 year. Subjects with comorbid bipolar disorder showed the greatest response and demonstrated improvement in MADRS scores as well (Marazziti et al. 2005).

Olanzapine has also been studied in Gilles de la Tourette syndrome (GTS), a disorder characterized by motor and vocal tics and frequently including obsessive and compulsive symptoms. Olanzapine has been noted in case reports to have benefit in treatment of the obsessive-compulsive features, as well as the tics (Van den Eynde et al. 2005). In a small (N = 4) double-blind, placebo-controlled crossover trial, olanzapine was compared with pimozide for the treatment of GTS. Olanzapine demonstrated positive effects at 5-mg and 10-mg doses, compared with pimozide doses of 2 mg or 4 mg, over 52 weeks (Onofrj et al. 2000). However, given the small sample size of this study, further research is needed to support a potential role for olanzapine in GTS.

Overall, olanzapine has demonstrated benefit as an adjunctive agent in the treatment of several anxiety disorders. In OCD and GTS, there have been open-label studies that have shown benefit, and in small double-blind studies, there have been generally positive, although ultimately equivocal, results. Further research, including head-to-head trials and more long-term studies, is needed to fully evaluate the efficacy of olanzapine and other second-generation antipsychotic medications in OCD (Ballon et al. 2007).

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) is a clinically significant disorder with symptoms of reexperiencing a traumatic event, avoidance of situations associated with the trauma, and increased arousal. To qualify for the diagnosis, a patient must have experienced or witnessed a serious event that threatened injury or death or threatened physical integrity (American Psychiatric Association 2000). Clinical observations of such patients show that they have periods of insomnia, nightmares, perceptual disturbances, sensory illusions, and suspiciousness. Some clinicians have noted nonspecific psychotic comorbidities. To date, SSRIs have been frequently used for PTSD, but there is no sole pharmacological standard of treatment. Not surprisingly, olanzapine has been assessed for symptoms of PTSD. As in some of the other disorders discussed in this chapter, the early data are limited and in pilot form.

The first study examined olanzapine in a double-blind, placebo-controlled study (2:1 randomization, olanzapine to placebo) at dosages ranging up to 20 mg/day. The research group reported no difference from placebo in this study but noted a high rate of placebo response (Butterfield et al. 2001). In the same year, a case series reported significant symptom reduction in the Clinician-Administered PTSD Scale, as well as in depression and anxiety scale (Hamilton Rating Scale for Depression and Hamilton Anxiety Scale) scores. In this relatively short (8-week) study, olanzapine was found to be helpful in this group of patients with combat-related trauma.

A third study examined the effect of olanzapine as an augmentation to SSRIs in patients not fully responsive to that treatment. This strategy is similar to that reported by Shelton et al. (2001) for refractory depression. Olanzapine or placebo was added to the patients' SSRI treatment. Active medication treatment led to statistically significantly greater reduction in PTSD symptoms, as assessed by PTSD scales, as well as in symptoms of anxiety and depression (Stein et al. 2002).

These early studies have similarities to the others for borderline personality disorder and anorexia

nervosa in that some success is noted in difficult-to-treat patient groups. Further controlled trials are needed to determine whether olanzapine's use for these indications is supported by an evidence base beyond the theoretical and anecdotal rationales currently used. Again, in the clinical arena, the treating psychiatrist would need to weigh the evidence and alternative treatments before proceeding.

SIDE EFFECTS AND TOXICOLOGY

The adverse effects of olanzapine in clinical use are consistent with the preclinical studies predicting few neurological effects. EPS, as manifested by dystonic reactions and parkinsonism, are uncommon, although these may be seen in patients who are sensitive to antipsychotics, such as patients with Parkinson's disease. In Phase II and III clinical trials, olanzapine-treated groups generally showed an improvement in EPS from baseline, reflecting the fact that most of the subjects had previously taken typical neuroleptics. In a large multinational comparison study (Tollefson et al. 1997), olanzapine produced fewer treatment-emergent neurological adverse effects than haloperidol for parkinsonism (14% vs. 38%) and akathisia (12% vs. 40%). In another study (Volavka et al. 2002), antiparkinsonian agents were prescribed to 13% of both clozapine- and olanzapine-treated subjects, compared with 32% of risperidone-treated patients.

The reduction of EPS is predictive of decreased risk of tardive dyskinesia, the most problematic of the common adverse effects of classic neuroleptics. To date, the accumulated experience with atypical antipsychotics indicates that tardive dyskinesia is 10- to 15-fold less common, at an annual rate of 0.52% of olanzapine-treated patients compared with 7.45% of haloperidol-treated patients, based on pooled data from long-term comparison trials (Beasley et al. 1999).

A major adverse effect found during treatment with olanzapine is weight gain. This is a serious concern because persons with schizophrenia are more likely than the general population to be obese, and weight gain may contribute to nonadherence to antipsychotic treatment, leading to increased risk for relapse. With the decrease in neurological side effects with second-generation antipsychotic agents, metabolic effects have emerged as a major risk for patients and a focus of consideration for clinicians. The relative degree of weight gain associated with first- and second-generation antipsychotics was studied in a comprehensive meta-analysis by Allison et al. (1999). Estimates of weight change associated with standardized doses over 10 weeks were calculated from published data from 81 studies. Clozapine produced the greatest weight gain (4.45 kg), followed by olanzapine (4.15 kg). By comparison, risperidone was associated with a gain of 2.1 kg, haloperidol was associated with a gain of 1.08 kg, and patients lost 0.74 kg while taking placebo. In long-term treatment, 30%–50% of patients may gain more than 7% of body weight, with low pretreatment weight and good clinical response associated with more weight gain.

Efforts involving use of other pharmacotherapies to combat weight gain have largely been unsuccessful. Sibutramine, an SNRI, has been shown to be an effective weight-loss agent and has been tested as an adjunct to behavioral modification for management of olanzapine- and clozapine-induced weight gain in double-blind, placebo-controlled trials. In the olanzapine study (Henderson et al. 2005), there was an average 8-pound weight loss compared with placebo, while in the clozapine study (Henderson et al. 2007), there was no statistical difference from placebo. Unfortunately, there have been case reports of sibutramine-induced psychosis (Rosenbohm et al. 2007; Taflinski and Chojnacka 2000), so its use in the psychotic disorder population must be carefully monitored. Other agents, including H_2 antagonists such as famotidine, have also been studied. In a double-blind trial in first-episode patients, famotidine given prophylactically had no benefit in preventing weight gain (Poyurovsky et al. 2004). Additionally, a trial of fluoxetine in first-episode schizophrenia patients yielded the same results (Poyurovsky et al. 2002). Small studies have shown modest positive results with the SNRI reboxetine (Poyurovsky et al. 2003) and the H_2 antagonist nizatidine (Atmaca et al. 2003).

A recent post hoc analysis of first-episode patients in Spain indicated that use of the orally disintegrating formulation of olanzapine might result in decreased weight gain (Arranz et al. 2007). This hypothesis was first proposed by de Haan et al. (2004) in a report of a small nonrandomized study in which adolescents switched from conventional olanzapine to sublingual dissolvable olanzapine lost an average of 6.6 kg in 16 weeks. The authors suggested that differential effects on serotonergic receptors in the gut, particularly at the pylorus, might be responsible for their findings, but larger randomized studies are needed on this topic.

Small studies using metformin, an agent known to decrease hepatic glucose output, have tested the possibility that it may help patients either lose weight or remain at the same weight while receiving olanzapine or other second-generation antipsychotics. In a double-blind, placebo-controlled trial (Baptista et al. 2006), patients were given 10 mg of olanzapine and randomly assigned to receive either metformin or placebo for 14 weeks. No differences between groups were seen in body mass index or waist circumference. There was a modest improvement in overall glucose levels and in measures of glucose homeostasis (homeostasis model assessment for insulin resistance [HOMA-IR]), but no change was seen in lipid levels. A follow-up study conducted by the same group (Baptista et al. 2007) demonstrated similar results, although in the second study, small differences in weight gain between the groups were found, with the metformin group losing an average of 1.5 kg and showing decreased leptin levels, while the placebo group maintained a consistent weight. In a double-blind, placebo-controlled trial in adolescents who had gained weight after 1 year of treatment with a second-generation antipsychotic (olanzapine, risperidone, or quetiapine), the addition of metformin resulted in statistical differences in waist circumference, body mass index, and overall weight gain (Klein et al. 2006). HOMA-IR scores were significantly decreased, and the number of subjects requiring referral for a glucose tolerance test was reduced, among the subjects who received metformin. These equivocal results suggest that further research is needed on adjunctive agents to help with the metabolic complications often seen with olanzapine.

Weight gain is an even greater concern in the treatment of children and adolescents, who may be exposed to medication for a longer time and are concerned with body image. After 12 weeks of treatment with olanzapine, hospitalized adolescent patients gained 7.2±6.3 kg, approximately twice the weight gain experienced by those taking risperidone; 19 of 21 patients (90%) gained more than 7% of their body weight (Ratzoni et al. 2002). These findings in patients younger than 18 years have been confirmed by Findling et al. (2003), who reported an average 6.5-kg weight gain in their assessment of schizophrenic patients over 8 weeks.

Concurrently with the attention to weight gain with second-generation antipsychotics, other metabolic effects have been noted. Reports of glucose intolerance, hyperglycemia, hyperlipidemia, diabetes, and diabetic ketoacidosis have surfaced, mostly associated with clozapine and olanzapine therapy. Cases reported to the FDA Drug Surveillance System and published cases of olanzapine-associated diabetes and hyperglycemia were reviewed by Koller and Doriswamy (2002). Two hundred eighty-nine cases were identified, of which 225 (78%) were new-onset diabetes, 100 (35%) involved ketosis or acidosis, and 23 (8%) patients died. Most cases developed within 6 months of initiation of olanzapine therapy. Many cases occurred in the first month of therapy, indicating that weight gain alone did not mediate the occurrence of diabetes-related problems. On the basis of the temporal relation between metabolic changes and the introduction and withdrawal of olanzapine, the young age of patients affected, and the number of reports, the authors concluded that the data suggested that olanzapine was causally related to the development or worsening of diabetes. A similar conclusion about clozapine and diabetes was reported earlier (Koller et al. 2001). Because case studies and reports by clinicians to regulatory agencies may reflect reporting bias, controlled studies comparing the development of metabolic disorders are needed to clarify whether these are related to the underlying psychosis, causally related to drug treatment in general, or specifically related to individual agents.

Studies that used large health system databases have been published linking use of antipsychotics with subsequent diagnoses of diabetes or use of hypoglycemic agents. These studies show increased risk of development of type 2 diabetes following the use of olanzapine and clozapine relative to the use of risperidone or typical antipsychotics or compared with matched untreated persons (Gianfrancesco et al. 2002; Koro et al. 2002a; Sernyak et al. 2002).

While olanzapine has been associated with weight gain and type 2 diabetes, there have also been reports of diabetic ketoacidosis (DKA), a condition more often associated with type 1 diabetes mellitus. These reports first appeared in the literature in 1999 (Gatta et al. 1999; Goldstein et al. 1999; Lindenmayer and Patel 1999). In a review of 45 published cases of DKA associated with atypical antipsychotic medications, 42% of cases were related to olanzapine, 44% were related to clozapine, and 6% each were related to risperidone and quetiapine (Jin et al. 2004). The onset of DKA was not associated with weight gain, though 80% of the patients were overweight prior to initiating treatment. The overall incidence of DKA is unknown; however, given the potential morbidity and mortality associated with this acute condition, close monitoring is critical, as DKA was the first presenting sign of diabetes in 42% of reported cases and generally required an intensive care unit admission. In a review of California Medicaid data on cases of risperidone- and olanzapine-associated DKA, Ramaswamy et al. (2007) found a higher incidence of DKA for olanzapine than for risperidone and noted that the risk increased with duration of treatment with olanzapine.

Another metabolic adverse effect seen with olanzapine is the development of dyslipidemia, often in association with weight gain. In a large British patient database, olanzapine conferred a fivefold increase in the rates of dyslipidemia over an untreated control condition and a threefold increase over conventional antipsychotics, whereas risperidone did not increase the risk (Koro et al. 2002b).

Sedation is frequent at the start of therapy with olanzapine but diminishes as patients develop tolerance for this side effect. In long-term treatment, the incidence of sedation is about 15%, similar to that of haloperidol. Anticholinergic effects occur during treatment but at rates only slightly higher than those of placebo, and they rarely lead to treatment discontinuation. Mild elevations of liver enzymes may be seen in some patients, but these are stable or decline over time without progression to hepatic dysfunction. Prolactin elevations observed during olanzapine treatment occur early in the course of treatment, and levels are much lower than those seen with risperidone or classic antipsychotic treatment. However, prolactin concentrations may exceed normal levels in patients taking 30 mg/day or more of olanzapine. Leukopenia is rare and occurs at a rate similar to that seen with other typical and atypical antipsychotics, but olanzapine does not cause agranulocytosis, even in patients who developed this effect while taking clozapine. In animal toxicology studies and in clinical trials, no QTc prolongation was observed, and other cardiovascular effects are rarely of clinical importance.

In summary, olanzapine is a well-tolerated antipsychotic agent with a low rate of EPS and diminished risk for tardive dyskinesia. Weight gain is common and can lead to discontinuation by choice or by clinician decision because of long-term health concerns. Patients should be monitored for the development of type II diabetes and dyslipidemia. Studies addressing weight gain are progressing, and new strategies may emerge in the near future.

DRUG–DRUG INTERACTIONS

Olanzapine is metabolized primarily via glucuronidation and via oxidation by CYP1A2 (see section "Pharmacokinetics and Disposition" earlier in this chapter). Other drugs that affect the activity of these metabolic pathways would therefore be expected to affect olanzapine pharmacokinetics. Indeed, drugs that inhibit CYP1A2 activity have been shown to decrease olanzapine clearance, thereby increasing olanzapine plasma concentrations.

Fluvoxamine, a known inhibitor of CYP1A2, has been shown to inhibit olanzapine metabolism in

several studies. A study of 10 healthy male smokers receiving 11 days of fluvoxamine administration (50–100 mg) resulted in an 84% increase in maximal olanzapine concentrations (C_{max}) and a 119% increase in AUC_{0-24} compared with olanzapine administered with placebo. In this study, olanzapine clearance decreased 50%, and apparent volume of distribution decreased approximately 45%. The C_{max} of olanzapine's metabolite 4'-*N*-desmethylolanzapine decreased 64%, and its AUC_{0-24} decreased 77%. No change in half-life was observed in either olanzapine or 4'-*N*-desmethylolanzapine, suggesting that fluvoxamine inhibited olanzapine's first-pass metabolism (Maenpaa et al. 1997). Another study found that in a population of patients receiving olanzapine, those also receiving fluvoxamine (*n* = 21) had, on average, a 2.3-fold higher concentration per dose ratio than did those not receiving fluvoxamine (*n* = 144) (Weigmann et al. 2001). A separate case report indicated that a patient who discontinued ciprofloxacin (also a CYP1A2 inhibitor) while receiving olanzapine experienced an approximately twofold decrease in olanzapine concentrations (Markowitz and DeVane 1999).

Fluoxetine and imipramine, although not known to be significant inhibitors of CYP1A2, when coadministered with olanzapine have been associated with statistically significant but small changes in olanzapine pharmacokinetics. Coadministration of fluoxetine resulted in a 15% decrease in olanzapine clearance and an 18% increase in C_{max}, with no significant difference in the half-life of olanzapine (Callaghan et al. 1999). Coadministration of imipramine resulted in an approximately 14% increase in olanzapine C_{max} and a non–statistically significant increase in AUC of 19% (Callaghan et al. 1997).

Inducers of the CYP1A2 enzyme increase olanzapine clearance, thereby decreasing olanzapine systemic exposure. Carbamazepine, an inducer of several CYP enzymes (including 1A2), affects olanzapine disposition. A study in healthy volunteers showed that 18 days of carbamazepine therapy (200 mg twice daily) resulted in significantly higher clearance (32.6 vs. 47.6 L/hour) and apparent volume of distribution (1,190 vs. 1,400 L/kg) but significantly lower C_{max} (11.7 vs. 8.8 μg/L), AUC (336 vs. 223 h*μg/L), and half-life (26.0 vs. 20.8 hours) after a single 10-mg dose of olanzapine (Lucas et al. 1998). In one case report, the discontinuation of carbamazepine was associated with a 114% increase in olanzapine concentrations (Licht et al. 2000).

Smoking, also known to induce CYP1A2, can affect olanzapine disposition. A study comparing 19 male smokers with 30 male nonsmokers found that olanzapine clearance in smokers was 23% higher than that in nonsmokers (Callaghan et al. 1999). A population pharmacokinetic analysis of 910 patients receiving olanzapine found that clearance among nonsmokers was 37% lower in men and 48% lower in women than it was in the corresponding group of smokers (Patel et al. 1996). A smaller analysis of healthy volunteers also found higher drug clearances among smokers (Patel et al. 1995). The polycyclic aromatic hydrocarbons in cigarette smoke are responsible for inducing the aryl hydrocarbon hydroxylases and thus lead to enzymatic induction (Desai et al. 2001). Thus, dosage adjustments might be needed when a patient who smokes is placed in a smoke-free inpatient unit, even if adequate nicotine replacement is provided.

A recent study suggested that probenecid, a nonspecific inhibitor of uridine diphosphoglucuronate-glucuronosyltransferase (UDPGT), can affect the disposition of a single 5-mg olanzapine dose. Following probenecid administration, a statistically significant increase of 19% occurred in olanzapine C_{max}, an increase of 26% occurred in olanzapine AUC (*P* = 0.002), and an increase of 57% occurred in the absorption rate constant, indicating a faster rate of absorption. Clearance was not significantly altered by probenecid coadministration. Because probenecid may also inhibit the P-glycoprotein efflux transporter, this alternative mechanism may be contributing to this drug interaction (Markowitz et al. 2002). It is not known whether other UDPGT inhibitors also will affect olanzapine disposition, although in vitro testing with valproic acid did not show an interaction (Eli Lilly 2006).

In vitro studies suggest that olanzapine does not significantly inhibit the activity of the CYP enzymes

1A2, 3A, 2D6, 2C9, or 2C19 (Ring et al. 1996a). In vivo studies suggest that olanzapine does not affect the disposition of aminophylline (Macias et al. 1998), diazepam, alcohol, imipramine (Callaghan et al. 1997), warfarin, biperiden, or lithium (Callaghan et al. 1999; Demolle et al. 1995).

CONCLUSION

After review of the research focused on olanzapine, it is clear that this compound, which has been approved for use in the United States since 1997, has wide utility and is a step forward from the traditional antipsychotic medications. In addition to the positive effect on a broad group of symptoms of schizophrenia, olanzapine has now been approved for treatment of mania, both acute and long term, in bipolar disorder. Recent research has shown that there may be benefit to disorders beyond psychosis (e.g., borderline personality disorder, anorexia, PTSD, OCD, Tourette syndrome) with olanzapine. The extension of uses of olanzapine is in many ways allowed by the low rates of movement disorders. The lack of dystonia, parkinsonism, and tardive dyskinesia leads to greater acceptability in chronic schizophrenia and has encouraged clinicians and investigators to find patients earlier in the course of their illness, thus reducing the duration of untreated psychosis and perhaps decreasing the number of patients who develop psychosis (McGlashan et al. 2003). The low rate of movement disorders has been a major factor in moving forward with treatment of mood disorders and nonpsychotic illnesses.

As noted in the section on side effects, olanzapine is not free of adverse effects, even though they are outside the movement disorder arena. Weight gain and metabolic disturbances are of significant concern and are the objects of intense research—in areas of both pathophysiology and prevention/treatment.

In addition to providing better treatment for schizophrenia and other disorders, olanzapine's actions in the brain have provided new avenues of research in the exploration of pathophysiology of psychiatric disease. As noted earlier in this chapter, olanzapine's effects on glutamate measures and neurotensin may open new avenues of treatment.

In conclusion, olanzapine is a psychotropic medication that was first approved for the treatment of psychosis related to schizophrenia. It has become a widely used medication for schizophrenia as well as other disorders. As noted, metabolic side effects are of concern and are the object of intense research. The future holds significant interest for understanding side effects, learning more about the effect of olanzapine on different syndromes, and gaining knowledge about the pathophysiology of psychiatric disease.

Chapter 30. Quetiapine

HISTORY AND DISCOVERY

Quetiapine is a second-generation antipsychotic (SGA) developed and subsequently marketed by AstraZeneca. In preclinical trials, quetiapine showed both the features associated with antipsychotic efficacy and a low rate of motor effects (Goldstein 1999; Nemeroff et al. 2002). The Phase III placebo-controlled clinical trials necessary for product registration confirmed this preclinical impression and demonstrated that quetiapine was efficacious in treating the manifestations of psychosis (Arvanitis and Miller 1997; Small et al. 1997). Of note, these studies also reported a low rate of treatment-emergent extrapyramidal side effects (EPS) with quetiapine use across a wide range of dosages that was comparable to the rate among placebo recipients. Quetiapine was approved in 1997 by the U.S. Food and Drug Administration (FDA) for the treatment of schizophrenia. Approval for use in Europe and in other countries worldwide has followed. Further clinical trials in patients with mania (McIntyre et al. 2005; Vieta et al. 2005) and patients with bipolar depression (Calabrese et al. 2005; Thase et al. 2006) led the FDA to approve additional indications for quetiapine's use in the acute and maintenance treatment of bipolar disorder. Most recently, the FDA has also approved a slow-release formulation of quetiapine for the treatment of schizophrenia (Kahn et al. 2007; Möller et al. 2007; Peuskens et al. 2007). Quetiapine is an established antipsychotic with broad efficacy and good tolerability, particularly with respect to EPS (Miodownik and Lerner 2006).

STRUCTURE–ACTIVITY RELATIONS

Quetiapine is an SGA of the dibenzothiazepine class. It has a complex neuropharmacology, with binding at brain receptors of several classes (Goldstein 1999). Its binding profile, in comparison with that of several other antipsychotics, is shown in Table 30–1. Of considerable interest is the fact that quetiapine has a relatively low binding profile for dopamine type 2 (D_2) receptors (Kapur et al. 2000a, 2000b; Kufferle et al. 1997; Seeman and Tallerico 1998; Stephenson et al. 2000). Indeed, considering the idea that an antipsychotic needs to occupy 60% or more of D_2 receptors in order to be clinically efficacious (Kapur et al. 2000b), quetiapine's low D_2 binding—typically approximately 30%—is noteworthy.

In attempting to reconcile this apparently subtherapeutic D_2 receptor antagonism with the well-recorded efficacy of quetiapine as an antipsychotic, Kapur and colleagues proposed an elegant *kiss and run hypothesis* for quetiapine's mechanisms of action (Kapur et al. 2000a). In a series of studies, they found that when D_2 receptor occupancy with quetiapine was measured with positron emission tomography (PET) at shorter intervals (4 hours and 6 hours) than the conventional 12 hours after the last dose was taken, quetiapine did indeed show high D_2 occupancy. They found that in contrast to other antipsychotics, quetiapine had a more rapid "run-off" from D_2 receptors; that is, there was rapid dissociation of the D_2 receptors (Kapur et al. 2000a). This was proposed to account for the discrepancy between observations of clinical potency and pharmacodynamic subthreshold receptor binding. This kiss-and-run theory is also put forward to explain the consistent observation of low rates of EPS and lack of increased prolactin levels during treatment with quetiapine (Nemeroff et al. 2002).

Quetiapine also, like clozapine, has strong binding at 5-hydroxytryptamine (serotonin) type 2 receptors (5-HT_2 receptors). This profile contrasts with its relatively weak affinity for other subclasses of the serotonin receptor family (Goldstein 1999). Quetiapine also has strong affinity for α_1-noradrenergic receptors. This antagonism may relate to its propensity to induce postural hypotension—especially during rapid dose titration. Additionally, quetiapine has strong antagonism at histamine type 1 (H_1) receptors. This most likely relates to its sedative effect. Weight gain during quetiapine therapy may also emanate from H_1 receptor antagonism. However, this structure–activity relationship is less clear than the association between H_1 antagonism and sedation.

Relatively less is known about quetiapine's effects on other aspects of neurochemistry that are thought to be of relevance (but not central) to antipsychotic activity. Some studies have shown that SGAs can induce brain cell proliferation (*neurogenesis*) in experimental animals (Lieberman et al. 2006). The evidence for quetiapine in this regard is sparse. Also, little is known about the effect of quetiapine on brain neurotrophins. One study (Xu et al. 2002) reported that quetiapine could reverse reductions in levels of brain-derived neurotrophic factor in an animal model. There is accumulating evidence that other SGAs may also increase brain neurotrophins (Buckley et al. 2007).

PHARMACOKINETICS AND DISPOSITION

Quetiapine is absorbed in the gastrointestinal tract, and its absorption is unaffected by food. Peak blood levels are achieved in about 2 hours, and effective plasma levels are sustained for

approximately 6 hours (DeVane and Nemeroff 2001). This provides the basis for the usual clinical regimen of twice-daily dosing. However, Chengappa et al. (2003b) conducted a short-term trial comparing once-daily dosing versus twice-daily dosing in patients with schizophrenia or schizoaffective disorder. The dosing profiles were equivalent in terms of efficacy and tolerability. Using PET, Mamo et al. (2008) found comparable plasma levels and D_2 receptor occupancy between the immediate-release and the extended-release formulation.

Quetiapine is metabolized by cytochrome P450 (CYP) 3A4 to inactive metabolites. Although genetic variations are not clearly described for the CYP3A4 enzyme, drug interactions with inhibitors and inducers of CYP3A4 are likely to be clinically significant. The anticonvulsants carbamazepine and phenytoin are common examples of CYP3A4 inducers, and in their presence quetiapine doses may need to be increased due to accelerated drug clearance (Potkin et al. 2002a, 2002b; Strakowski et al. 2002). Ritonavir, erythromycin, ketoconazole, and nefazodone are potent inhibitors of CYP3A4, and their use requires caution when they are coadministered with quetiapine; while they are used, doses of quetiapine should be lowered (de Leon et al. 2005; Wong et al. 2001).

In 2007, the FDA approved an extended-release (XR) formulation of quetiapine for the treatment of schizophrenia on the basis of results from clinical trials (Kahn et al. 2007; Lindenmayer et al. 2008). These studies compared the efficacy and tolerability of XR and regular immediate-release (IR) formulations. Overall, the results of these studies indicate that quetiapine XR given once daily (at dosages of 400–800 mg/day) is effective for the treatment of schizophrenia. The XR formulation appears to have efficacy comparable to that of the IR formulation. The XR formulation was also similar in tolerability to the IR formulation in clinical trials, with perhaps some marginal benefit in causing less sedation. Quetiapine is excreted in the kidneys and is not affected by gender or smoking status (Thyrum et al. 2000). The metabolism of quetiapine is reduced by approximately 30% with advancing age (Goldstein 1999).

INDICATIONS AND EFFICACY

Quetiapine currently has the following FDA-approved indications:

- Schizophrenia
- Bipolar disorder

There are also reports of quetiapine's efficacy in treating other conditions, such as mood disorders in children and anxiety disorders, obsessive-compulsive disorder (OCD), and Parkinson's disease in adults. These uses have not been approved by the FDA. As a result of its use in the FDA indications and also in several unapproved circumstances, quetiapine is the most frequently prescribed antipsychotic in the United States at the time of writing. In this section of the chapter, we describe results of pivotal and recent studies of quetiapine for its FDA-approved indications. For completeness's sake and in recognition of quetiapine's use in nonapproved conditions, we also provide an account of some studies of subjects with other conditions. The use of any medication (in this case quetiapine) in situations that are not FDA-approved indications is not recommended for clinical practice.

Schizophrenia

The pivotal product registration trials and early trials of quetiapine (Arvanitis and Miller 1997; Borison et al. 1996; Copolov et al. 2000; King et al. 1998; Peuskens and Link 1997; Small et al. 1997) demonstrated that quetiapine is an efficacious antipsychotic for the treatment of schizophrenia. In the United States, short-term (6-week) trials compared quetiapine and placebo using quetiapine dosages of either 250 mg/day or 750 mg/day (Small et al. 1997) or daily dosages of 75 mg, 150 mg, 300 mg, or 750 mg (Arvanitis and Miller 1997); the latter trial also compared quetiapine and haloperidol. Similar to registration trials of other antipsychotics, these studies established a range of effective dosages for quetiapine. However, they provided no clear evidence of a dose-dependent increase in

efficacy (although post hoc analyses have suggested that higher doses of quetiapine are more efficacious). Additionally, because of the wide range of dosages used in these studies, the initial dosing recommendations for quetiapine in schizophrenia patients were unclear and were further complicated by a slow titration pattern. As a result, clinicians tended to favor the lower end of the quetiapine dosing range.

Subsequent studies helped refine quetiapine dosing strategies. Clinicians are also now using higher doses of quetiapine that are, on average, more consistent with those used in recent studies. Emsley et al. (2000) conducted a fixed-dose comparison trial of quetiapine at 600 mg/day versus haloperidol at 20 mg/day. The drugs had similar efficacy in this 8-week trial of patients who were a priori deemed "partial responders." More recent studies have shown that the titration of quetiapine can be quicker than heretofore considered. Pae et al. (2007) compared a rapid titration strategy (beginning at 200 mg/day, increasing to 800 mg/day by day 4) with a more conventional dosing strategy (50 mg/day on day 1, up to 400 mg/day by day 5). The two groups fared equally well in terms of tolerability during this 14-day study. The higher-dose, more rapid titration strategy had a marginal advantage in overall efficacy. Information on the use of high dosages (>800 mg/day) of quetiapine is very limited. Pierre et al. (2005) reported on quetiapine's efficacy in a sample of treatment-refractory schizophrenic patients at dosages of up to 1,200 mg/day. More fixed-dose comparison studies with quetiapine are needed to assist clinicians in further refining their dosing strategies with this agent.

Although two meta-analyses cast doubt on quetiapine's efficacy with respect to first-generation antipsychotics (FGAs; Davis et al. 2003; Geddes et al. 2000), most studies comparing quetiapine with haloperidol or chlorpromazine report that the agents have similar efficacy in treating schizophrenia (Emsley et al. 2000; Peuskens and Link 1997; Small et al. 1997). Given that today most clinicians in the United States select one of the SGAs, comparisons between quetiapine and other SGAs are perhaps more meaningful. Several studies have been published that inform this consideration. A 4-month open-label trial of quetiapine and risperidone in a heterogeneous patient population —although predominantly subjects with schizophrenia and related psychotic disorders—showed overall comparability between the two agents (Mullen et al. 2001). Zhong et al. (2006) reported on an 8-week comparative trial of quetiapine and risperidone in a chronic schizophrenia patient population. The average quetiapine dosage was 525 mg/day and the average risperidone dosage was 5.2 mg/day. The drugs proved similar in efficacy. Quetiapine-treated patients had fewer EPS, lower prolactin levels, and fewer sexual side effects. Weight gain was similar in both treatment groups. Quetiapine was more sedating and was more frequently associated with dry mouth than was risperidone. Another study comparing quetiapine and risperidone, a 6-month study, reported better efficacy with risperidone (Potkin et al. 2006). Quetiapine was associated with more polypharmacy in that study. Kinon et al. (2006) reported on a 6-month double-blind comparative trial of quetiapine and olanzapine. Quetiapine-treated patients were less likely to complete the study. Relapse rates were comparable overall in the two treatment groups. More weight gain occurred in olanzapine recipients. As yet, no studies have directly compared quetiapine with either ziprasidone or aripiprazole in the treatment of schizophrenia.

The most extensive comparative evaluation of quetiapine and other SGAs comes from the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) schizophrenia studies. In the phase 1 study, in which the effectiveness of several antipsychotics was examined over 18 months, more quetiapine-treated patients than olanzapine-treated patients had discontinued treatment by 18 months (78% vs. 64%), and a similar (not statistically significant) trend was seen in comparisons of quetiapine versus risperidone, ziprasidone, or perphenazine (Lieberman et al. 2005). In the phase 2 study of efficacy pathways for patients with persistent symptoms, discontinuation rates favored clozapine and olanzapine over risperidone and quetiapine (McEvoy et al. 2006). The results from the tolerability pathways were more mixed, with similar efficacy observed between quetiapine and other agents (Stroup et al. 2007). The findings relating to quetiapine's relative adverse-effects profile in this

formative study are presented later in this chapter (see "Side Effects and Toxicology"). Another interesting analysis from the CATIE schizophrenia studies (Stroup et al. 2007) examined how those patients originally assigned to the perphenazine arm of the phase 1 study fared. In this analysis, switching to quetiapine was more efficacious than switching to any of the other agents. Much of the efficacy and tolerability differences among agents observed in the CATIE schizophrenia studies have been attributed to differential dosing profiles.

An analogous comparative trial of quetiapine, risperidone, and olanzapine was conducted with patients experiencing their first episode of psychosis—the Comparison of Atypicals in First Episode Psychosis (CAFÉ) study. Here, discontinuation rates were similar with all three drugs over the course of the 1-year trial (McEvoy et al. 2007). The comparative dosing profiles for quetiapine, risperidone, and olanzapine in the CAFÉ study and the CATIE schizophrenia study, referenced against the FDA-approved dosages, are shown in Table 30–2.

The use of quetiapine in patients with prodromal features of schizophrenia has not yet been studied. Little is known about quetiapine's efficacy in treatment-refractory patients. In a subanalysis of more severely ill patients in an 8-week comparative trial of quetiapine and haloperidol, quetiapine showed a small benefit over haloperidol (Buckley et al. 2004). The open-label observational study by Pierre et al. (2005) also showed some benefit for quetiapine at high doses in treatment-refractory patients. Sacchetti et al. (2004) reported a 50% response rate in a small sample of patients who had been refractory to prior treatment with FGAs.

Information on the long-term efficacy of quetiapine is limited. Open-label follow-up in extension studies for up to 4 years has shown sustained efficacy, with the average dosage of quetiapine recorded at 450 mg/day (Buckley et al. 2004). A recently conducted 6-month placebo-controlled study of quetiapine (the new XR formulation) in schizophrenia patients showed a clinically beneficial effect on relapse prevention (Peuskens et al. 2007). Several studies have demonstrated improvements in cognitive performance during quetiapine therapy in patients with schizophrenia (Sax et al. 1998; Velligan et al. 2002, 2003).

Mood Disorders

There is evidence that quetiapine is an effective and well-tolerated antipsychotic for treating patients with bipolar mania and bipolar depression. Initial evidence for mood effects were derived from observations on mood assessment items in the pivotal schizophrenia trials. In one of the pivotal product registration trials evaluating quetiapine (Small et al. 1997), both high and low doses of quetiapine were significantly better than placebo in improving Brief Psychiatric Rating Scale (BPRS) measures of mood disturbance in patients with schizophrenia (Goldstein 1999). In an analysis of another pivotal trial comparing five dosages of quetiapine in patients with schizophrenia (Arvanitis

and Miller 1997), patients receiving 150 mg/day showed significant improvement in BPRS-derived measures of mood. In the Quetiapine Experience with Safety and Tolerability (QUEST) study, quetiapine was compared with risperidone in a 4-month open-label, flexible-dose trial (Mullen et al. 2001). This study included patients with schizophrenia, schizoaffective disorder, bipolar disorder, and depression. At week 16 the mean dosage of quetiapine was 317 mg/day, and the mean dosage of risperidone was 4.5 mg/day. Mean improvement on the Hamilton Rating Scale for Depression was significantly greater in quetiapine recipients than in risperidone recipients.

More recent studies have confirmed that quetiapine is efficacious for the acute treatment of mania and bipolar depression. In short-term placebo-controlled trials, quetiapine as a monotherapy reduced symptoms of mania. Quetiapine has also been assessed as an add-on agent with either lithium or valproic acid. Calabrese et al. (2005) and Thase et al. (2006) have studied quetiapine in patients with bipolar depression. In an 8-week trial, Calabrese et al. (2005) compared two dosages of quetiapine (300 mg/day and 600 mg/day) versus placebo. Both dosages were efficacious, with improvements observed across the full range of depressive and anxiety symptoms. Fifty-eight percent of patients met a priori criteria for treatment response. Additionally, this antidepressant effect was observed with a once-daily dosage regimen. In a subsequent similar study of the same two dosages (300 mg/day and 600 mg/day; Thase et al. 2006), quetiapine was again compared with placebo in an 8-week trial in patients with bipolar depression. Again, both dosages of quetiapine showed efficacy across a broad range of depressive symptoms. These two studies led to FDA approval of quetiapine for treating bipolar depression. Furthermore, Dorée et al. (2007) recently reported that in a pilot study (n = 20) quetiapine was an efficacious augmenting agent for major depression. There is also emerging information that quetiapine's metabolite may have mood-regulating effects (Goldstein et al. 2007).

Other Conditions and Patient Populations

The two studies on bipolar depression cited above (Calabrese et al. 2005; Thase et al. 2006) also showed improvements in anxiety symptoms with quetiapine. Additionally, the sedative/calming effect of quetiapine is well described in a variety of product registration trials (Buckley et al. 2007; Chengappa et al. 2003a). Thus, there is interest in whether quetiapine may be helpful in treating anxiety states, and off-label use of quetiapine in patients with anxiety disorders has been reported. This is a complicated issue. A clinical trial of quetiapine to treat anxiety disorders is ongoing (www.clinicaltrials.gov). There is also published information from a small study showing that quetiapine reduces symptoms of both anxiety and posttraumatic stress disorder (Hamner et al. 2003).

Information has also been published on the use of quetiapine as an augmenting agent with selective serotonin reuptake inhibitors in treating OCD (Dell'Osso et al. 2006; Denys et al. 2007). Dell'Osso et al. (2006) showed that quetiapine provided benefit in a small case series of patients with OCD. Denys et al. (2007) analyzed published augmentation studies in OCD patients and found that quetiapine augmentation was efficacious and, interestingly, was more efficacious in patients who were receiving lower doses of a selective serotonin reuptake inhibitor (SSRI) than in those receiving higher SSRI doses.

Quetiapine appears to be an effective treatment for children with schizophrenia or bipolar disorder (Barzman et al. 2006; DelBello et al. 2007; McConville et al. 2000). DelBello et al. (2007) recently reported therapeutic effects of quetiapine in a cohort of children who showed subsyndromal symptoms and were at risk for bipolar disorder but who did not actually meet diagnostic threshold criteria for a bipolar diagnosis. Quetiapine is also used more broadly for treating agitation in children (Findling et al. 2007).

Quetiapine has also been used in the elderly. McManus et al. (1999) reported baseline and 12-week data for 151 elderly patients (mean age, 76.8 years) who were treated in a 1-year open-label trial of quetiapine. Seventy percent of patients had some organic condition, predominantly Alzheimer's

disease, with the majority of remaining patients having a diagnosis of a functional psychosis such as schizophrenia, schizoaffective disorder, or delusional disorder. Fifty-two percent of all patients achieved a 20% or greater decline in BPRS total score. Quetiapine was well tolerated at a mean dosage of 100 mg/day. Zhong et al. (2007) reported a 10-week study comparing two dosages of quetiapine (100 mg/day and 200 mg/day) versus placebo in nursing home residents with dementia and agitation. Quetiapine at 100 mg/day was not efficacious, whereas quetiapine at 200 mg/day was efficacious for treating agitation. Quetiapine (100 mg/day) was also compared with risperidone (1.0 mg/day), olanzapine (5.5 mg/day), and placebo over 36 weeks in the CATIE Alzheimer's disease study (Schneider et al. 2006). This is the largest comparative study to date of the relative efficacy and tolerability of antipsychotics in elderly patients with Alzheimer's disease and related dementias. Overall, no effect was seen with any of the agents, and no differences were seen between the agents in terms of time to discontinuation of treatment for any reason.

Several neuropsychiatric conditions, the most notable being Parkinson's disease, are associated with the emergence of transient or sometimes persistent psychotic symptoms (Juncos 1999). The management of Parkinson's disease is further complicated by hallucinations associated with levodopa therapy. Older antipsychotics were effective in relieving psychotic symptoms in these patients, but their use also aggravated the disease. Quetiapine may be a preferred treatment in patients with Parkinson's disease (Friedman 2003; Friedman et al. 1998; Juncos 1999; Targum and Abbott 2000). In a 24-week study of quetiapine in 29 patients with Parkinson's disease (mean age, 73 years), Juncos (1999) observed that treatment with quetiapine at a mean dosage of 62.5 mg/day improved psychosis without causing deterioration in motor function. Menza et al. (1999) reported similar results using quetiapine at dosages of 12.5–150 mg/day in three patients with Parkinson's disease whose medication was switched from clozapine to quetiapine. In another study, 25 patients with Parkinson's disease were switched from either clozapine or olanzapine to quetiapine; 17 (68%) of the patients were switched to quetiapine without a worsening of psychosis (Friedman et al. 1998). Targum and Abbott (2000) reported that quetiapine stopped visual hallucinations in 6 of 10 patients with Parkinson's disease, but delusions were less responsive to treatment. In a study by Merims et al. (2006), both clozapine and quetiapine showed efficacy in treating psychosis in Parkinson's disease patients. Clozapine was marginally more efficacious but was associated with a high adverse-effect burden.

Agitation is a core aspect of several conditions. There is, of course, no FDA-approved drug for treating agitation, and use of antipsychotics for nonapproved clinical indications is strongly discouraged. Nevertheless, antipsychotics have been used to manage agitation in a variety of circumstances. Currier et al. (2006) reported an interesting study of quetiapine in agitated patients in the emergency room. Here, Currier and colleagues reported that quetiapine could be used as an acute antiagitation agent if the dose titration is judicious. Postural hypotension was observed in this study. Other studies of quetiapine and agitation reflect post hoc analyses of clinical trials and report benefits in treating hostility both in adults with schizophrenia (Chengappa et al. 2003a) or bipolar disorder (Buckley et al. 2007) and in children with conditions associated with disruptive, hostile behaviors (Barzman et al. 2006; Findling et al. 2007).

SIDE EFFECTS AND TOXICOLOGY

To illustrate the profile of adverse effects that are typically seen with quetiapine, we have reproduced herein the results from a recent clinical trial of 8 weeks' duration (Zhong et al. 2006) in which schizophrenic patients received an average quetiapine dosage of 525 mg/day (Table 30–3). Overall, quetiapine was well tolerated in this study, and only 6% of patients discontinued treatment due to adverse effects. The most commonly recorded side effects of quetiapine treatment in this study were somnolence (26% of patients), headache (15%), weight gain (14%), dizziness (14%), and dry mouth (12%).

Somnolence is a common side effect of quetiapine that most likely relates to its antihistaminergic effects. It occurs early in treatment and generally decreases over time. It may persist in some patients, however. It may also cause patients to stop taking their medication, because sedation is generally a poorly tolerated side effect. In the bipolar depression study by Calabrese et al. (2005), somnolence was observed in 24% of patients receiving quetiapine at a dosage of 300 mg/day and in 27% of patients receiving 600 mg/day. Dizziness is another troublesome side effect when it occurs. It may be associated with postural hypotension—an effect that is of even greater concern. Sometimes, like sedation, this can cause discontinuation of quetiapine therapy.

There is growing concern about antipsychotic-induced weight gain and metabolic disturbances (Allison et al. 1999; Brooke et al. 2009; Newcomer et al. 2002). Quetiapine is associated with weight gain, although current evidence indicates that neither the frequency nor the magnitude of the weight gain effect is as great as that seen with clozapine or olanzapine. On the other hand, the weight-effects profile of quetiapine is not as favorable as that of either ziprasidone or aripiprazole (Brooke et al. 2009). The lack of data on long-term maintenance treatment with quetiapine makes it hard to quantify its weight-effects liability with robust objectivity over the course of illness (Brooke et al. 2009).

In a report of open-label extension studies of patients with schizophrenia who continued taking quetiapine for up to 18 months, patients experienced on average a 1.74-kg increase over their baseline weight (Brecher et al. 2000). Weight gain was most pronounced—and, conversely, least

pronounced—in those who were underweight and markedly obese, respectively. This is consistent with a lower body mass index being a predictor for weight gain in genetic studies of weight gain in schizophrenic patients (Müller and Kennedy 2006). In the 8-week comparative study by Zhong et al. (2006), weight gain that was clinically significant (a 7.7% increase above baseline weight) was observed in 10.4% of patients receiving quetiapine and in 10.5% of patients receiving risperidone. The average weight gain was 1.6 kg for quetiapine recipients and 2.12 kg for risperidone recipients. In the phase 1 CATIE schizophrenia study, quetiapine had a moderate effect on weight (and other aspects of the metabolic profile) compared with the other agents in that major study (Lieberman et al. 2005). Those data are shown in Table 30–4. In the first-episode CAFÉ study, quetiapine had a more favorable weight-effects profile than did olanzapine or risperidone. Fifty percent of patients taking quetiapine gained weight, compared with 80% of those taking olanzapine and 58% of those taking risperidone. Interestingly, females taking quetiapine were less likely than males to gain weight in this 1-year study of patients treated for their first episode of psychosis (J. K. Patel, P. F. Buckley, S. Woolson, et al., "Metabolic Profiles of Second-Generation Antipsychotics in Early Psychosis: Findings From the CAFE Study" (submitted for publication), October 2008). It is also important to consider quetiapine's propensity to induce weight gain among bipolar patients (especially because these patients may also be taking lithium or valproic acid). In the BOLDER (BipOLar DEpRession) study of patients with bipolar depression (Calabrese et al. 2005), 9% of patients receiving quetiapine at a dosage of 600 mg/day and 8.5% of patients receiving 300 mg/day had a 7% or greater increase in weight. The average weight gains for quetiapine-treated patients in this study were 1.6 kg and 1.0 kg for the 600-mg/day and 300-mg/day groups, respectively.

Note. Hb = hemoglobin; SE = standard error. *P* values for laboratory values and for the change in weight are based on ranked analysis of covariance with adjustment for whether patient had an exacerbation in the preceding 3 months and the duration of exposure to the study drug in phase 1. Mean values for metabolic factors (other than weight change) were also adjusted for duration of exposure to study drug.

We have less information on other aspects of quetiapine's metabolic effects, in part because only recently conducted studies have included careful measurements of fasting glucose and lipid levels. In the bipolar depression study by Calabrese et al. (2005), the mean increases in glucose levels at study endpoint were 6 mg/dL and 3 mg/dL with quetiapine dosages of 600 mg/day and 300 mg/day,

respectively. In the comparative study of quetiapine and risperidone in the treatment of schizophrenia (Zhong et al. 2006), the mean increases in fasting glucose levels from baseline to study endpoint were 1.8 mg/dL with quetiapine and 5.6 mg/dL with risperidone. The metabolic profile of quetiapine appeared moderate in the phase 1 CATIE schizophrenia study (see Table 30–4). Meyer and Stahl (2009) examined the biology of and reviewed the available data concerning distinct metabolic profiles in the context of antipsychotic therapy. Newcomer et al. (2009) have presented data from a euglycemic clamp study of quetiapine. They found little evidence of insulin insensitivity, although it was noteworthy that there was a small signal of raised triglyceride levels in this study. This was also found in another recent naturalistic study (de Leon et al. 2007). Overall, quetiapine appears to carry a risk of causing weight gain and other metabolic disturbances. This risk appears to be variable in patients, and it is not as pronounced as the risk with either clozapine or olanzapine. The results of an intriguing study in which the addition of quetiapine to clozapine resulted in lower rates of diabetes (Reinstein et al. 1999) have not been replicated.

Two side-effect characteristics that distinguish quetiapine from other SGAs and from FGAs are its low rates of prolactin elevation and low rates of EPS. Consistently, quetiapine is associated with a low risk of raising prolactin levels (Hamner et al. 1996; Lieberman et al. 2005; Small et al. 1997; Zhong et al. 2006). In the quetiapine versus risperidone schizophrenia study (Zhong et al. 2006), mean prolactin levels were reduced by 11.5 mg/mL in quetiapine-treated patients, whereas they were increased by 35.5 mg/mL in risperidone-treated patients. Similar effects on prolactin levels were observed with quetiapine in both the CATIE and CAFÉ schizophrenia studies (Lieberman et al. 2005; McEvoy et al. 2007).

The low-EPS advantage of quetiapine is compelling and consistent across studies. Indeed, in the SPECTRUM switch study (Larmo et al. 2005), switching to quetiapine from either an FGA or an SGA was associated with a robust reduction in EPS. This low propensity for EPS was also seen in the bipolar depression studies (Calabrese et al. 2005; Thase et al. 2006). Moreover, quetiapine's EPS advantage has propelled it to the status of being the agent of choice among neurologists who treat psychosis in patients with Parkinson's disease.

The potential of quetiapine to induce cataracts is still unknown. The relationship of antipsychotic therapy in general to cataract formation is unclear (Isaac et al. 1991; Johnson 1998). A large pragmatic trial that includes regular specialist ophthalmological examinations to investigate the incidence of cataract formation during therapy with quetiapine is nearing completion (www.clinicaltrials.gov). It is hoped that this study will shed new light on the issue. At present it appears that most clinicians do not obtain specialist eye examinations when prescribing quetiapine.

Abnormalities in thyroid hormone levels were a concern that emanated from early trials of quetiapine (Arvanitis and Miller 1997). This no longer appears to be a clinically meaningful risk, and recent studies have not shown any consistent evidence of thyroid dysfunction with quetiapine use (Kelly and Conley 2006).

Quetiapine's prescribing information (AstraZeneca 2008a, 2008b) possesses a warning similar to that required in the prescribing information of many other antipsychotics concerning cardiovascular risks. These potential cardiac risks, especially prolongation of the QTc interval (the ventricular depolarization and repolarization phase, or QT phase, of the electrocardiogram corrected for heart rate), have been comprehensively reviewed by Glassman and Bigger (2001). However, there is no evidence of any heightened QTc risk with quetiapine (Lieberman et al. 2005). It is also suggested that quetiapine might have abuse potential (Pierre et al. 2005; Pinta and Taylor 2007). Given that it is used more broadly than other SGAs, this observation merits further consideration and vigilance.

Overall, the adverse-effect profile of the XR formulation is similar to that of the IR formulation. As is the case with all SGAs, there is little information about the effects of quetiapine during pregnancy. A

prospective study by McKenna et al. (2005) studied a sample of pregnant women in Canada, Israel, and England treated with SGAs, which was matched to a comparison group of pregnant women who were not exposed to these agents. Among them were 36 women treated with quetiapine. The pregnancy outcomes in the exposed and comparison groups were not significantly different, with the exceptions of the rate of low birthweight, which was 10% in exposed babies versus 2% in the comparison group (P = 0.05), and the rate of therapeutic abortions, which was 9.9% in exposed women versus 1.3% in the comparison group (P = 0.003). Atypical antipsychotics as a group did not appear to be associated with an increased risk for major malformations. Yaeger et al. (2006) reported that among 39 prospectively identified cases of fetal exposure to quetiapine, including the 36 in the study by McKenna et al. (2005), no congenital malformations were found.

CONCLUSION

Quetiapine is now a well-established and widely prescribed antipsychotic. There is strong evidence for efficacy in all current FDA-approved indications: the treatment of schizophrenia and bipolar disorder. This agent is also used extensively under circumstances not approved by the FDA (off-label use), and evidence for efficacy in some of these uses is reviewed (but *not* endorsed clinically) in this chapter. Major clinical trials of quetiapine for several unapproved uses are ongoing (www.clinicaltrials.com). Quetiapine possesses a particularly favorable profile with respect to D_2 receptor antagonism–related side effects. Its low propensity to cause EPS is well established, and studies have consistently shown that quetiapine does not appear to elevate prolactin levels. These two differential tolerability advantages are important when considering whether a patient might benefit from switching from his or her current medication to quetiapine (Weiden and Buckley 2007). On the other hand, the weight-gain effects and metabolic profile of quetiapine are of concern. However, the weight and metabolic risks have yet to be clearly determined for quetiapine relative to other SGAs. Based on current evidence, it appears to have an intermediate position among the SGAs with respect to metabolic risk. Overall, quetiapine represents a useful addition to the psychopharmocological armamentarium, with established efficacy and a broadly favorable tolerability profile.

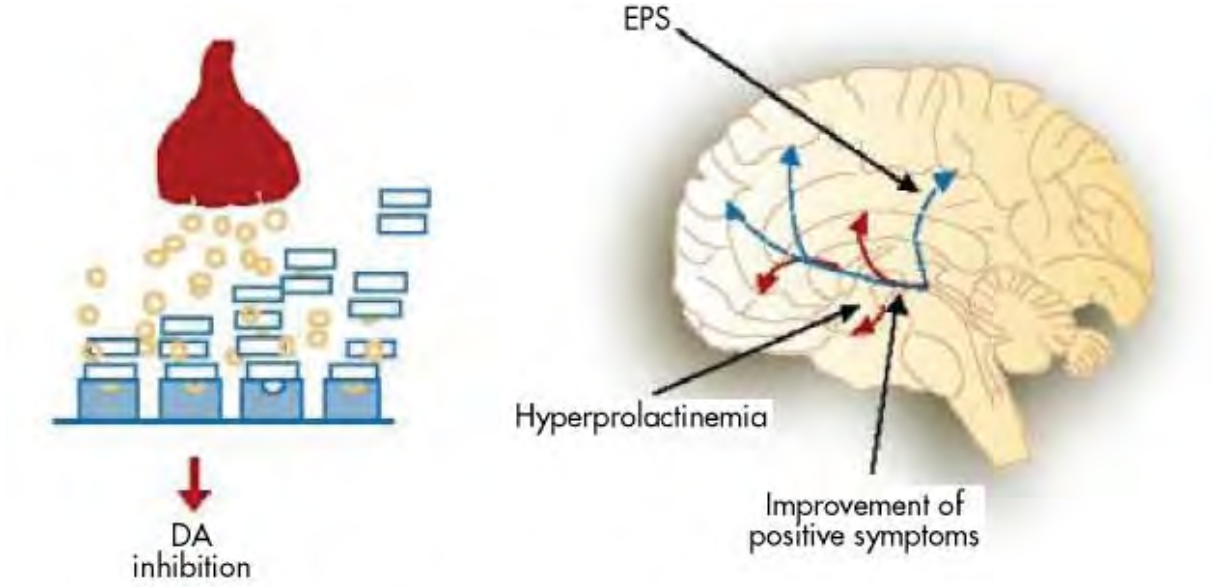
Chapter 31. Aripiprazole

HISTORY AND DISCOVERY

Aripiprazole is a dihydroquinolinone antipsychotic agent. Chemically, it is unrelated to phenothiazine, butyrophenone, thienobenzodiazepine, or other antipsychotic agents. Pharmacologically, it exhibits a novel mechanism of action, combining partial agonist activity at dopamine$_2$ (D_2), dopamine$_3$ (D_3), and serotonin$_{1A}$ (5-HT_{1A}) receptors with antagonist activity at serotonin$_{2A}$ (5-HT_{2A}) and D_2 receptors (Burris et al. 2002; Jordan et al. 2002). The development and approval of aripiprazole represent a significant event in the history of antipsychotic agents, as it potentially represents another significant innovation following the introduction of first-generation, or typical, antipsychotic drugs and second-generation, or atypical, antipsychotic drugs in the pharmacology and mechanism of action of therapeutic agents for psychotic disorders.

Although effective in alleviating psychotic symptoms and preventing their recurrence, the typical agents are ineffective in up to 40% of patients with schizophrenia. Even in patients who respond, typical antipsychotics lack efficacy against the negative symptoms of schizophrenia, such as anhedonia and apathy. The typical agents are also associated with a considerable burden of extrapyramidal side effects (EPS) and other side effects, including tardive dyskinesia and hyperprolactinemia. Among patients with first-episode schizophrenia, parkinsonian side effects have been identified as a predictor of discontinuation of antipsychotic treatment (Robinson et al. 2002).



The atypical agents are partially effective against negative as well as positive symptoms and are also associated with fewer EPS. Nevertheless, individual atypical agents are associated with side effects such as weight gain, hyperprolactinemia, QTc prolongation, and alterations in glucose and lipid levels (Allison et al. 1999; Glassman and Bigger 2001; Koro et al. 2002a, 2002b; McIntyre et al. 2001). These side effects may reduce patient adherence to treatment and so increase the long-term risk of acute schizophrenic relapse (Fleischhacker et al. 1994; Kurzthaler and Fleischhacker 2001). They may also be associated with harmful medical sequelae.

The development of aripiprazole was guided by prevailing hypotheses of the etiology of schizophrenia. The dopamine (DA) hypothesis (Seeman and Niznik 1990) proposes that abnormalities in dopaminergic neurotransmission in the brain cause the symptoms of schizophrenia. In its current form, the DA hypothesis suggests that schizophrenia involves a biphasic disturbance in dopaminergic pathways, leading to altered function in different anatomical regions (Davis et al. 1991; Pycock et al. 1980; Weinberger 1987). According to this model, underactivity of the mesocortical dopaminergic pathway leads to hypodopaminergic activity in the frontal cortex, whereas overactivity in the mesolimbic pathway causes increased dopaminergic neurotransmission. The latter is presumed to cause positive or psychotic symptoms, while the former is believed to underlie negative symptoms and cognitive impairment. Another influential hypothesis suggests that the activity of dopaminergic pathways is modulated by serotonergic neurons that project from the raphe nuclei to the corpus striatum and the frontal cortex. In the striatum, serotonin release inhibits DA, while in the frontal cortex it has a modulatory effect on pyramidal neurons and can affect glutamate release.

These hypotheses help to explain several features of typical and atypical antipsychotic agents. All these agents behave as full D_2 antagonists. Their actions in the mesolimbic pathway would therefore be expected to benefit patients with schizophrenia by reducing positive symptoms. D_2 antagonism in the other dopaminergic pathways would, however, be expected to cause unwanted side effects, including

exacerbation of negative symptoms (mesocortical pathways), EPS and tardive dyskinesia (nigrostriatal tract), and hyperprolactinemia (tuberoinfundibular pathway) (Figure 31–1).

FIGURE 31–1. Conventional dopamine (DA) antagonist activity: effect on positive symptoms, extrapyramidal side effects (EPS), and prolactin levels.

Similarly, the serotonin (5-HT) hypothesis may help to explain why the atypical agents, which have antagonist activity at 5-HT_{2A} receptors, are associated with fewer EPS and do not exacerbate (and, in fact, partially alleviate) negative symptoms and cognitive impairment (Leysen et al. 1993; Millan 2000; Rao and Möller 1994; Richelson 1999).

On the basis of aripiprazole's unique pharmacodynamic profile—partial agonist activity (rather than full antagonist activity) at both dopaminergic (D_2; Burris et al. 2002) and serotonergic (5-HT_{1A}; Jordan et al. 2002) receptors, and full antagonist activity at 5-HT_{2A} receptors (McQuade et al. 2002)—it was anticipated that aripiprazole treatment would be associated with a reduced burden of unwanted D_2 antagonist activity in the mesocortical, nigrostriatal, and tuberoinfundibular pathways—the activity associated with some of the side effects of typical and atypical antipsychotic agents (Figure 31–2).

PHARMACOLOGICAL PROFILE

Aripiprazole exhibits potent partial agonist activity at D_2 (Burris et al. 2002) and 5-HT_{1A} (Jordan et al. 2002) receptors, together with potent antagonist activity at 5-HT_{2A} receptors. It also has high affinity for D_3 receptors; moderate affinity for dopamine$_4$ (D_4), serotonin$_{2C}$ (5-HT_{2C}), serotonin$_7$ (5-HT_7), α_1-adrenergic, and histamine$_1$ (H_1) receptors and the serotonin reuptake site (SERT); and negligible affinity for cholinergic muscarinic receptors (Table 31–1). The active metabolite of aripiprazole, dehydroaripiprazole, exhibits a similar affinity at D_2 receptors and has not been shown to have a pharmacological profile that is clinically significantly different from that of the parent compound.

PHARMACOKINETICS AND DISPOSITION

Aripiprazole is available for oral administration as tablets in strengths of 2, 5, 10, 15, 20, and 30 mg. The effective dose range is 10–30 mg/day for schizophrenia patients and 15–30 mg/day for bipolar I disorder patients. A rapidly disintegrating oral formulation of aripiprazole is available in 10-mg and 15-mg strengths. In addition, aripiprazole is available in a 1-mg/mL nonrefrigerated oral solution. Aripiprazole is taken once daily with or without food and is well absorbed after oral administration, with peak plasma concentrations occurring within 3–5 hours. Absolute oral bioavailability is 87%. An injectable form of aripiprazole for intramuscular (IM) use to provide rapid control of agitation in adults with schizophrenia or bipolar mania was approved by the U.S. Food and Drug Administration (FDA) in September 2006. Aripiprazole injection is available in single-dose, ready-to-use vials containing 9.75 mg aripiprazole in 1.3 mL of diluent (7.5 mg/mL); the recommended initial dose is 9.75 mg IM. Time to the peak plasma concentration is 1–3 hours after IM injection, and the absolute bioavailability of a 5-mg injection is 100%. The mean maximum concentration achieved after an IM dose is on average 19% higher than the maximum plasma concentration (C_{max}) of the oral tablet. While the systemic exposure over 24 hours is generally similar for aripiprazole administered as an IM injection and as an oral tablet, the aripiprazole area under the curve (AUC) in the first 2 hours after an IM injection is 90% greater than the AUC after the same dose

in a tablet (Otsuka Pharmaceutical 2006).

In plasma, aripiprazole and its major metabolite, dehydroaripiprazole, are both more than 99% bound to proteins, primarily albumin. Aripiprazole is extensively distributed outside the vascular system, and human studies demonstrating dose-dependent occupancy of D_2 receptors have confirmed that aripiprazole penetrates the brain. Elimination half-lives for aripiprazole and dehydroaripiprazole are 75 hours and 94 hours, respectively.

Aripiprazole is metabolized primarily in the liver. Two hepatic cytochrome P450 (CYP) enzymes, 2D6 and 3A4, catalyze dehydrogenation to dehydroaripiprazole. Therefore, coadministration with inducers or inhibitors of these CYP enzymes may require dosage adjustment of aripiprazole. The active metabolite accounts for 40% of drug exposure, but the predominant circulating moiety is the parent drug. Aripiprazole does not undergo direct glucuronidation and is not a substrate for the following CYP enzymes: 1A1, 1A2, 2A6, 2B6, 2C8, 2C9, 2C19, and 2E1. Interactions with inhibitors or inducers of these enzymes, or with chemicals related to cigarette smoke, are therefore unlikely to occur.

Patient demographic characteristics have not been shown to have any clinically significant impact on the pharmacokinetics of aripiprazole. In general, dosing does not need to be adjusted in respect of a patient's age, gender, race, smoking status, or hepatic or renal function.

Following a single oral dose of ^{14}C-labeled aripiprazole, approximately 25% and 55% of the administered radioactivity were recovered in the urine and feces, respectively. Less than 1% of unchanged aripiprazole was excreted in the urine, and approximately 18% of the oral dose was recovered unchanged in the feces.

MECHANISM OF ACTION

Aripiprazole has partial agonist activity at D_2 receptors, a feature that distinguishes it from all other currently available antipsychotics, which are full D_2 antagonists. In vitro studies in D_2 receptors in rat striatal membranes (A. Inoue et al. 1997) and rat anterior pituitary slices (T. Inoue et al. 1996) showed that aripiprazole acts as an antagonist when coadministered in the presence of a DA agonist. In other in vitro studies using cloned D_2 receptors from either rat (Lawler et al. 1999) or human (Burris et al. 2002), aripiprazole dose-dependently inhibited isoproterenol-stimulated cyclic adenosine monophosphate (cAMP) synthesis. In these studies, aripiprazole acted as an agonist in the absence of DA, although its maximal agonist activity was less than that of DA, a full agonist.

The activity of aripiprazole at D_2 receptors has also been studied in animal models of schizophrenia (Kikuchi et al. 1995). Aripiprazole exhibits DA antagonist activity in an animal model of hyperdopaminergic activity. In the intact rat with repetitive stereotyped behavior (stereotypy) induced by apomorphine, aripiprazole inhibits stereotypy and locomotion (Kikuchi et al. 1995). This agent may therefore be expected to inhibit hyperdopaminergic activity in the mesolimbic pathway of patients with schizophrenia and so, like other available agents, provide antipsychotic efficacy against the positive symptoms of schizophrenia. On the other hand, in animal models of hypodopaminergic activity, such as the reserpinized rat, aripiprazole has D_2 receptor agonist activity. Because aripiprazole may display either D_2 antagonist activity under hyperdopaminergic conditions or D_2 agonist activity under hypodopaminergic conditions, this agent may be less likely than other antipsychotics to cause excessive D_2 antagonism.

Aripiprazole may offer further therapeutic benefits through modulation of central serotonergic pathways. Preclinical studies showed that aripiprazole has antagonist activity at 5-HT_{2A} receptors (McQuade et al. 2002), a feature that has been associated with reductions in EPS (Meltzer 1999) and negative symptoms. In vitro studies also have shown that aripiprazole has partial agonist activity at 5-HT_{1A} receptors (Jordan et al. 2002), a feature that has been associated with improvement in negative, cognitive, depressive, and anxiety symptoms (Millan 2000).

Other receptor activity may explain some of the side effects of aripiprazole; for example, nausea/vomiting may be explained by its DA agonist effects, whereas orthostatic hypotension and mild sedation/weight gain are likely related to its antagonist activity at α_1-adrenergic and H_1 receptors, respectively.

INDICATIONS AND EFFICACY

In the United States, aripiprazole is approved by the FDA for: acute and maintenance treatment of schizophrenia in adults and in adolescents 13–17 years of age; for acute and maintenance treatment of manic and mixed episodes associated with bipolar I disorder with or without psychotic features in adults and pediatric patients 10–17 years of age; as adjunctive therapy to either lithium or valproate for the acute treatment of manic and mixed episodes associated with bipolar I disorder with or without psychotic features in adults and pediatric patients 10–17 years of age; and as an adjunctive therapy to antidepressants for the acute treatment of major depressive disorder in adults. Additionally, aripiprazole injection is indicated for the acute treatment of agitation associated with schizophrenia or bipolar disorder (manic or mixed) in adults (Abilify [aripiprazole] U.S. Full Prescribing Information).

The efficacy of aripiprazole as a treatment for acute relapse of schizophrenia was demonstrated in four short-term (4-week) double-blind, placebo-controlled studies. Among these was a pivotal Phase III parallel-group multicenter study with four treatment arms comparing aripiprazole (15 mg or 30 mg) with placebo (Kane et al. 2002). Haloperidol (10 mg/day) was used as an active control to confirm the study population's responsiveness to antipsychotic therapy. The total group of patients who were randomized to treatment (N = 414) comprised 282 patients with schizophrenia and 132 with schizoaffective disorder. Compared with placebo, aripiprazole at either dose produced statistically significant improvements from baseline in the following psychometric scores: Positive and Negative Syndrome Scale (PANSS)—Total, PANSS positive subscale, PANSS-derived Brief Psychiatric Rating Scale (BPRS)—Core, Clinical Global Impression (CGI)–Severity of Illness, and CGI–Improvement. Aripiprazole 15 mg also significantly improved PANSS negative score compared with placebo. Both doses of aripiprazole produced measurable improvement rapidly, with improvement from placebo detectable on psychometric scales by week 2. This trial suggests that at doses of 15 mg and 30 mg, aripiprazole provides effective symptom control in patients with acute relapse of schizophrenia.

Similar findings emerged from another pivotal short-term multicenter Phase III study involving 404 inpatients with an acute relapse of schizophrenia or schizoaffective disorder (Potkin et al. 2003). Patients were randomly assigned to aripiprazole 20 mg, aripiprazole 30 mg, risperidone 6 mg, or placebo for 4 weeks. Compared with placebo, aripiprazole at both doses and risperidone treatment produced statistically significant improvements in scores on standard scales designed to measure antipsychotic efficacy. Likewise, responder rates (with response defined as a score of 1 or 2 on the CGI–Improvement) for both doses of aripiprazole and for risperidone were significantly higher than those for placebo. This study showed that aripiprazole at doses of 20 mg and 30 mg was significantly more effective than placebo.

The antipsychotic efficacy of aripiprazole in acute relapse of schizophrenia was also demonstrated in two Phase II dose-ranging studies, both of which used haloperidol as an active control. In one study, 307 patients with an acute relapse of schizophrenia were randomized to aripiprazole 2 mg, 10 mg, or 30 mg daily or haloperidol 10 mg/day (Daniel et al. 2000). All three doses of aripiprazole produced improvements in efficacy measures from baseline, and the 30-mg dose produced statistically significant improvement compared with placebo on all illness scores, including CGI–Severity, BPRS–Total, BPRS–Core, PANSS–Total, and PANSS positive and negative subscales. Similarly, in a Phase II dose-titrating study, aripiprazole 5–30 mg was superior to placebo in improving BPRS–Total, BPRS–Core, CGI–Severity, and PANSS–Total scores (Petrie et al. 1997).

Results from the three 4-week fixed-dose studies discussed above were pooled for analysis with those of an additional 6-week placebo-controlled, fixed-dose study of aripiprazole at doses of 10 mg, 15 mg, and 20 mg (Lieberman et al. 2002). The pooled analysis involving 898 patients randomized to aripiprazole showed that at all investigated doses greater than 2 mg, aripiprazole exhibited antipsychotic efficacy superior to placebo. Onset of efficacy was rapid, with improvement on psychometric scores detectable within 1 week of starting treatment. These pooled efficacy results demonstrate that doses of 10–30 mg represent an effective therapeutic range for aripiprazole treatment.

The antipsychotic efficacy of aripiprazole in patients with schizophrenia has been further confirmed in two long-term double-blind, randomized, controlled multicenter trials. A 26-week placebo-controlled study in

310 patients with chronic stable schizophrenia investigated the efficacy of aripiprazole 15 mg in relapse prevention (Pigott et al. 2003). Patients who had been symptomatically stable on other antipsychotic medications for 3 months or longer were taken off these medications and randomly assigned to aripiprazole 15 mg or placebo for up to 26 weeks and observed for relapse (defined as a score of 5 [minimally worse] on the CGI–Improvement, a score of 5 [moderately severe] on the hostility or uncooperativeness items of the PANSS, or a 20% increase in the PANSS–Total score). Aripiprazole treatment significantly increased the time to relapse and resulted in significantly fewer relapses at endpoint compared with placebo (34% vs. 57%). From week 6 of therapy, PANSS–Total and PANSS positive subscale scores were significantly more improved with aripiprazole than with placebo.

Another study evaluated the long-term efficacy of aripiprazole when treatment was maintained for up to 52 weeks (Kasper et al. 2003). Patients with acute relapse of schizophrenia (N = 1,294) were randomized to aripiprazole 30 mg/day (n = 861) or haloperidol 10 mg/day (n = 433). Significantly more aripiprazole-treated patients were still taking the medication and were responding to treatment at weeks 8, 26, and 52 than were haloperidol-treated patients. Both treatments produced sustained improvements in the PANSS–Total and PANSS positive subscale scores from baseline. However, aripiprazole produced significantly greater improvements in negative and depressive symptoms at weeks 26 and 52 and was associated with significantly lower scores on all EPS assessments compared with haloperidol.

The efficacy of aripiprazole monotherapy in antipsychotic-resistant schizophrenia was evaluated in a 6-week double-blind, randomized trial in 300 patients who had failed to improve in a prospective 4- to 6-week open trial with olanzapine or risperidone (Kane et al. 2007). Subjects were randomly assigned to aripiprazole (15–30 mg/day) or perphenazine (8–64 mg/day). After 6 weeks, there was no statistical difference between the two groups on efficacy measures; 27% of aripiprazole-treated patients and 25% of perphenazine-treated patients were classified as responders (30% improvement from baseline or CGI–Improvement score of 1 or 2). Compared with aripiprazole, perphenazine was associated with a higher rate of EPS and elevated serum prolactin.

The efficacy of aripiprazole in the treatment of schizophrenia in pediatric patients (ages 13–17 years) was evaluated in a 6-week placebo-controlled trial of outpatients who met DSM-IV (American Psychiatric Association 1994) criteria for schizophrenia and had a PANSS score ≥70 at baseline (Findling et al. 2008). In this trial comparing two fixed doses of aripiprazole (10 mg/day or 30 mg/day) with placebo, aripiprazole was titrated starting from 2 mg/day to the target dose in 5 days in the 10 mg/day treatment arm and in 11 days in the 30 mg/day treatment arm. Of 302 patients, 85% completed the 6-week study. Both aripiprazole doses showed statistically significant differences from placebo in reduction in PANSS–Total score; the 30 mg/day dose was not shown to be more efficacious than the 10 mg/day dose. Adverse events occurring in more than 5% of either aripiprazole group and with a combined incidence at least twice the rate for placebo were extrapyramidal disorder, somnolence, and tremor. Mean body weight changes were –0.8, 0.0, and 0.2 kg for placebo, aripiprazole 10 mg, and aripiprazole 30 mg, respectively

The efficacy of aripiprazole in the treatment of acute manic episodes was established in two 3-week placebo-controlled trials in hospitalized patients who met DSM-IV criteria for bipolar I disorder with manic or mixed episodes (Keck et al. 2003; Sachs et al. 2006). These trials included patients with and without psychotic features and with and without a rapid-cycling course. The primary instrument used for assessing manic symptoms was the Young Mania Rating Scale (YMRS), an 11-item clinician-rated scale traditionally used to assess the degree of manic symptomatology. A key secondary instrument included the Clinical Global Impression–Bipolar (CGI-BP) scale. In both trials (n = 268; n = 248), aripiprazole was started at 30 mg/day, but the dosage could be reduced to 15 mg/day on the basis of efficacy and tolerability. Aripiprazole was superior to placebo in the reduction of YMRS total score and CGI-BP Severity of Illness score (mania). In a third large randomized, double-blind trial involving 347 patients (Vieta et al. 2005), aripiprazole was compared with haloperidol in the treatment of acute bipolar mania over a 12-week period. Significantly more patients remained in treatment and were classified as responders (50% reduction in YMRS score from baseline) at week 12 for aripiprazole (49.7%) than for haloperidol (28.4%). EPS adverse events were more frequent with haloperidol than with aripiprazole (62.7% vs.

24.0%).

The efficacy of adjunctive aripiprazole with concomitant lithium or valproate in the treatment of manic or mixed episodes was established in a 6-week placebo-controlled study (*N* = 384) with a 2-week lead-in mood stabilizer monotherapy phase in adult patients who met DSM-IV criteria for bipolar I disorder. This study included patients with manic or mixed episodes and with or without psychotic features. Patients were initiated on open-label lithium or valproate at therapeutic serum levels and remained on stable doses for 2 weeks. At the end of 2 weeks, patients demonstrating inadequate response to lithium or valproate (YMRS total score 16 and ≤25% improvement on the YMRS total score) were randomized to receive either aripiprazole (15 mg/day with an increase to 30 mg/day as early as day 7) or placebo as adjunctive therapy with open-label lithium or valproate. In the 6-week placebo-controlled phase, adjunctive aripiprazole starting at 15 mg/day with concomitant lithium or valproate (in a therapeutic range of 0.6–1.0 mEq/L or 50–125 μg/mL, respectively) was superior to lithium or valproate with adjunctive placebo in the reduction of the YMRS total score and CGI-BP Severity of Illness score (mania). Seventy-one percent of the patients coadministered valproate and 62% of the patients coadministered lithium were on 15 mg/day at the 6-week endpoint.

Aripiprazole monotherapy was also evaluated in the treatment of nonpsychotic depressive episodes associated with bipolar I disorder. The results of two identically designed 8-week randomized, double-blind, placebo-controlled multicenter studies were reported by Thase et al. (2008). Patients were randomly assigned to placebo or aripiprazole (initiated at 10 mg/day, then flexibly dosed at 5–30 mg/day based on clinical effect and tolerability). The primary endpoint was mean change from baseline to week 8 (last observation carried forward [LOCF]) in the Montgomery-Åsberg Depression Rating Scale (MADRS) total score. Although statistically significant differences were observed during weeks 1–6, aripiprazole did not achieve statistical significance versus placebo at week 8 in either study in the change in MADRS total score (primary endpoint). In addition, despite early statistical separation on the Clinical Global Impressions Bipolar Version Severity of Illness–Depression score (key secondary endpoint), aripiprazole was not superior to placebo at endpoint. Aripiprazole was associated with a higher incidence of akathisia, insomnia, nausea, fatigue, restlessness, and dry mouth versus placebo. More patients discontinued with aripiprazole versus placebo in both studies. Thus, aripiprazole monotherapy as dosed in this study design was not significantly more effective than placebo in the treatment of bipolar depression at endpoint (Thase et al. 2008).

To evaluate the long-term effectiveness of aripiprazole in delaying relapse in bipolar I disorder patients, a trial was conducted in patients meeting DSM-IV criteria for bipolar I disorder with a recent manic or mixed episode who had been stabilized on open-label aripiprazole and who had maintained a clinical response for at least 6 weeks (Keck et al. 2006). The first phase of this trial was an open-label stabilization period in which inpatients and outpatients were clinically stabilized (YMRS score ≤10 and MADRS score ≤13) and then maintained on open-label aripiprazole (15 or 30 mg/day, with a starting dose of 30 mg/day) for at least 6 consecutive weeks. One hundred sixty-one outpatients were then randomized in a double-blind fashion to either the same dose of aripiprazole they were on at the end of the stabilization and maintenance period or a switch to placebo and were then monitored for manic or depressive relapse. During the randomization phase, aripiprazole was superior to placebo on time to the number of combined affective relapses (manic plus depressive), the primary outcome measure for this study. The majority of these relapses were due to manic rather than depressive symptoms. Aripiprazole-treated patients had significantly fewer relapses than placebo-treated patients (25% vs. 43%). Aripiprazole was superior to placebo in delaying the time to manic relapse but did not differ from placebo in delaying time to depressive relapse. Significant weight gain (7% increase from baseline) was seen in 13% of the aripiprazole patients and none of the placebo patients. An examination of population subgroups did not reveal any clear evidence of differential responsiveness on the basis of age and gender; however, there were insufficient numbers of patients in each of the ethnic groups to adequately assess intergroup differences.

The efficacy of aripiprazole in the treatment of bipolar I disorder in pediatric patients (ages 10–17 years)

was evaluated in a 4-week placebo-controlled trial of outpatients (*N* = 296) who met DSM-IV criteria for bipolar I disorder manic or mixed episodes with or without psychotic features and had a YMRS score 20 at baseline. This double-blind, placebo-controlled trial compared two fixed doses of aripiprazole (10 mg/day or 30 mg/day) against placebo. The aripiprazole dose was started at 2 mg/day, which was increased to 5 mg/day after 2 days and to the target dose in 5 days in the 10 mg/day treatment arm and in 13 days in the 30 mg/day treatment arm. Both doses of aripiprazole were superior to placebo in change from baseline to week 4 on the YMRS total score. Although maintenance efficacy in pediatric patients has not been systematically evaluated, maintenance efficacy can be extrapolated from adult data, along with comparisons of aripiprazole pharmacokinetic parameters in adult and pediatric patients (Abilify [aripiprazole] U.S. Full Prescribing Information).

Aripiprazole is also available in an injectable formulation for IM administration. The efficacy of aripiprazole injection in controlling acute agitation was evaluated in three short-term (24-hour) randomized, double-blind, placebo-controlled studies in patients with schizophrenia (Andrezina et al. 2006; Tran-Johnson et al. 2007) and patients with bipolar disorder (manic or mixed) (Zimbroff et al. 2007), involving a total of 1,086 patients. The effectiveness of aripiprazole injection in controlling agitation was measured in these studies using several instruments, including the PANSS Excited Component (PANSS EC) and CGI–I scale. The primary efficacy measure used for assessing signs and symptoms of agitation was the change from baseline in the PANSS EC at 2 hours' postinjection. PANSS EC includes five items: poor impulse control, tension, hostility, uncooperativeness, and excitement. Aripiprazole injection was statistically superior to placebo (*P* 0.05) in all three studies, as measured with the PANSS EC. In the two studies in agitated patients with schizophrenia, injectable aripiprazole and IM haloperidol were compared with placebo. The injectable formulations of aripiprazole and haloperidol were both superior to placebo. In the study in agitated bipolar I disorder (manic or mixed) patients, aripiprazole injection and lorazepam injection were compared with placebo. Both active agents were superior to placebo. FDA-approved dosage preparations are as follows: 5.25 mg/0.7 mL, 9.75 mg/1.3 mL, and 15 mg/2.0 mL. The recommended initial dose of aripiprazole injection is 9.75 mg.

De Deyn et al. (2005) compared the efficacy, safety, and tolerability of aripiprazole against placebo in patients with psychosis associated with Alzheimer's disease (AD). This 10-week double-blind multicenter study randomized 208 outpatients (mean age = 81.5 years) with AD-associated psychosis to aripiprazole (*n* = 106) or placebo (*n* = 102). The initial aripiprazole dose of 2 mg/day was titrated upward (5, 10, or 15 mg/day) according to efficacy and tolerability. Evaluations included the Neuropsychiatric Inventory (NPI) Psychosis subscale and the BPRS, adverse event (AE) reports, EPS rating scales, and body weight measurement. Overall, 172 patients (83%) completed the study. The mean aripiprazole dose at study endpoint was 10.0 mg/day. The NPI Psychosis subscale score showed improvements in both groups (aripiprazole, –6.55; placebo, –5.52; *P* = 0.17 at endpoint). Aripiprazole-treated patients showed significantly greater improvements from baseline in BPRS Psychosis and BPRS–Core subscale scores at endpoint compared with placebo-treated patients. Somnolence was mild and was not associated with falls or accidental injury. There were no significant differences from placebo in EPS scores or in clinically significant electrocardiogram abnormalities, vital signs, or weight.

In another double-blind, multicenter study (Mintzer et al. 2007), 487 institutionalized patients with psychosis associated with AD were randomized to placebo or aripiprazole, 2, 5 or 10 mg/day. Primary efficacy assessment was the mean change from baseline to week 10 on the Neuropsychiatric Inventory–Nursing Home (NPI-NH) version Psychosis Subscale score. Aripiprazole 10 mg/day showed significantly greater improvements than placebo on the NPI-NH Psychosis Subscale (–6.87 vs. –5.13; *P* = 0.013) by analysis of covariance; CGI-S (–0.72 vs. –0.46; *P* = 0.031); BPRS Total (–7.12 vs. –4.17; *P* = 0.030); and NPI-NH Psychosis response rate (65% vs. 50%; *P* = 0.019). Aripiprazole 5 mg/day showed significant improvements versus placebo on BPRS and Cohen-Mansfield Agitation Inventory (CMAI) scores. Aripiprazole 2 mg/day was not efficacious. Four cases of cerebrovascular adverse events were reported in the aripiprazole 10 mg/day group, two in the 5-mg group, and one in the 2-mg group. No cerebrovascular adverse events were reported in the placebo group.

In 2005, the FDA issued a black box warning for second-generation antipsychotics based on increased mortality rates (4.5% vs. 2.6%) observed in patients with dementia-related psychosis treated with second-generation antipsychotics as compared with placebo over a modal duration treatment period of 10 weeks. This warning was extended in June 2008 to include all older conventional antipsychotic agents. No antipsychotic is currently approved in the United States for treating the behavioral and psychotic symptoms that frequently accompany dementia.

Nickel et al. (2006) conducted a double-blind, placebo-controlled study in 52 subjects (43 women and 9 men) meeting criteria for borderline personality disorder who were randomly assigned in a 1:1 ratio to 15 mg/day of aripiprazole (*n* = 26) or placebo (*n* = 26) for 8 weeks. Significant changes in scores on most scales of the Symptom Checklist (SCL-90-R), on the Hamilton Rating Scale for Depression (Ham-D), on the Hamilton Anxiety Scale (Ham-A), and on all scales of the State-Trait Anger Expression Inventory were observed in subjects treated with aripiprazole after 8 weeks. The improvements noted at 8 weeks of therapy were maintained at 18-month follow-up (Nickel et al. 2007).

Because of aripiprazole's partial DA agonist activity, there has been substantial interest in evaluating the utility of aripiprazole in reducing cravings and drug use in cocaine-, alcohol-, and amphetamine-abusing patients and as an augmentation strategy in patients with treatment-resistant depression. Tiihonen et al. (2007) conducted a study in individuals meeting DSM-IV criteria for intravenous amphetamine dependence (*N* = 53) who were randomly assigned to receive aripiprazole (15 mg/day), slow-release methylphenidate (54 mg/day), or placebo for 20 weeks. The study was terminated prematurely because of unexpected results of interim analysis. Contrary to the hypothesized result, patients who received aripiprazole treatment had significantly more amphetamine-positive urine samples than did patients in the placebo group, whereas patients who received methylphenidate had significantly fewer amphetamine-positive urine samples than patients who had received placebo. Studies in cocaine-abusing subjects are ongoing.

In a study in alcoholic patients (Anton et al. 2008) the efficacy and safety of aripiprazole was compared with placebo in a 12-week double-blind multicenter trial in 295 patients with alcohol dependence according to DSM-IV criteria. Patients were randomly assigned to treatment with aripiprazole (initiated at 2 mg/day and titrated to a maximum dose of 30 mg/day at day 28) or placebo after minimum 3 day abstinence during the screening period. The primary efficacy measure was percentage of days abstinent over 12 weeks. Discontinuations (40.3% vs. 26.7%) and treatment-related adverse events (82.8% vs. 63.6%) were higher with aripiprazole than with placebo. Mean percentage of days abstinent was similar between aripiprazole and placebo (58.7% vs. 63.3%; $P = 0.227$). Percentage of subjects without a heavy drinking day and the time to first drinking day were also comparable between groups, although the aripiprazole group had fewer drinks per drinking day (4.4 vs. 5.5 drinks; $P < 0.001$). The aripiprazole group showed a larger decrease in percentage carbohydrate-deficient transferrin, a biomarker of heavy alcohol consumption at weeks 4 (–14.91% vs. –2.23%; $P = 0.02$) and 8 (–16.92% vs. –5.33%; $P = 0.021$), although not at week 12 (–9.06% vs. –4.12%; $P = 0.298$). At study endpoint, aripiprazole-treated subjects reported more positive subjective treatment effects and less overall severity of alcohol dependence than placebo-treated subjects. Although there was no difference between aripiprazole and placebo on the primary endpoint, effects on the secondary outcomes suggest that further study of aripiprazole for treatment of alcohol dependence may be warranted at lower doses (Anton et al. 2008).

The efficacy of aripiprazole in the adjunctive treatment of major depressive disorder was demonstrated in two identical short-term (6-week) placebo-controlled trials of adult patients meeting DSM-IV criteria for major depressive disorder who had had an inadequate response to prior antidepressant therapy (1 to 3 courses) in the current episode. In both studies, a 7- to 28-day screening phase was followed by an 8-week prospective antidepressant treatment phase and a 6 week double-blind adjunctive treatment phase. During prospective antidepressant treatment, patients received one of several antidepressants (escitalopram, fluoxetine, paroxetine controlled-release, sertraline, or venlafaxine extended-release), each with single-blind adjunctive placebo. Patients with incomplete response (defined as 50% improvement on the 17-item version of the Hamilton Rating Scale for Depression [Ham-D-17], a final

Ham-D-17 score 14, and a Clinical Global Impressions Improvement rating of no better than minimal improvement) continued on the antidepressant and were randomly assigned to double-blind adjunctive placebo or adjunctive aripiprazole (2–15 mg/day with potent CYP2D6 inhibitors fluoxetine or paroxetine; 2–20 mg/day with all other antidepressants). The primary efficacy measure was mean change from end of prospective treatment to end of double-blind treatment (LOCF) in MADRS total score (analysis of covariance). A key secondary outcome was the Sheehan Disability Scale (SDS), a 3-item self-rated instrument used to assess the impact of depression on three domains of functioning (work/school, social life, and family life), with each item scored from 0 (not at all) to 10 (extreme).

In the first trial (Berman et al. 2007), a total of 178 patients were randomly assigned to adjunctive placebo and 184 to adjunctive aripiprazole in the double-blind adjunctive treatment phase. The mean change in MADRS total score was significantly greater with adjunctive aripiprazole (–8.8) than with adjunctive placebo (–5.8; *P*0.001). Adverse events that occurred in 10% or more of patients with adjunctive placebo or adjunctive aripiprazole were akathisia (4.5% vs. 23.1%), headache (10.8% vs. 6.0%), and restlessness (3.4% vs. 14.3%). Discontinuations due to adverse events were low with adjunctive placebo (1.7%) and adjunctive aripiprazole (2.2%); only one adjunctive aripiprazole–treated patient discontinued because of akathisia. About 1% of placebo recipients and 7.1% of aripiprazole recipients experienced weight gain of 7% or greater from baseline.

In the second trial (Marcus et al. 2008), 190 patients were randomly assigned to adjunctive placebo and 191 to adjunctive aripiprazole. The mean change in MADRS total score was significantly greater with adjunctive aripiprazole than with placebo (–8.5 vs. –5.7; $P = 0.001$). Remission rates were significantly greater with adjunctive aripiprazole than placebo (25.4% vs. 15.2%; $P = 0.016$) as were response rates (32.4% vs. 17.4%; $P < 0.001$). The mean SDS total score—the key secondary outcome measure—improved significantly more with adjunctive aripiprazole than with adjunctive placebo at endpoint (–1.3 vs. –0.7; $P = 0.012$). Adverse events occurring in 10% or more of patients with adjunctive placebo or aripiprazole were akathisia (4.2% vs. 25.9%), headache (10.5% vs. 9.0%), and fatigue (3.7% vs. 10.1%). Incidence of adverse events leading to discontinuation was low (adjunctive placebo [1.1%] vs. adjunctive aripiprazole [3.7%]). By the last study visit, continuing akathisia was reported in 25 (51%) of the 49 patients who had ever reported this symptom. Furthermore, the majority of akathisia (n = 38/49; 78%) was first reported during the first 3 weeks of treatment. Akathisia, at its maximum, was generally mild ($n = 12/49$; 25%) or moderate ($n = 33/49$; 67%) in severity, with few patients reporting akathisia as severe ($n = 4/49$; 8%). For those subjects whose akathisia resolved during the study ($n = 24$), 58% ($n = 14/24$) received dosage reduction and 42% ($n = 10/24$) received no intervention. Mean (SE) weight gain in the adjunctive aripiprazole group (1.47 ± 0.16 kg) was significantly greater than the placebo group (0.42 ± 0.17 kg; $P < 0.001$; LOCF). Weight gain of 7% or greater from baseline occurred in 0% of adjunctive placebo–treated patients and 3.4% of adjunctive aripiprazole–treated patients ($P = 0.031$).

These scientifically rigorous studies confirmed initial observations from case reports, retrospective chart reviews, and small open-label trials of the utility of aripiprazole in augmenting antidepressants in patients with major depressive disorder and led to the FDA approval for this indication in late 2007.

SIDE EFFECTS AND TOXICOLOGY

The safety and tolerability of antipsychotic therapy are important aspects of schizophrenia management, as they have an impact on treatment adherence and so on patients' risk of relapse and quality of life. Specific side effects seen with some antipsychotics, such as weight gain and hyperprolactinemia, may also have long-term implications for patient health.

A pooled analysis of safety and tolerability data from the five short-term studies (Marder et al. 2003; Stock et al. 2002) showed that aripiprazole treatment was well tolerated. The most commonly reported adverse events with aripiprazole were headache, insomnia, agitation, and anxiety; these were also the most frequently reported events in the placebo, haloperidol, and risperidone groups. The incidence of adverse events was similar in the aripiprazole and placebo groups. Akathisia, somnolence, and EPS were more common among patients receiving haloperidol than those receiving aripiprazole, while akathisia,

somnolence, and tachycardia were more frequent in the risperidone group than in the aripiprazole group. The adverse-event profile of aripiprazole did not vary according to patient characteristics of age, gender, and race, and no deaths were reported during the short-term studies. Data from the four fixed-dose studies showed that somnolence was the only adverse event seen with aripiprazole that was possibly dose-related. The overall incidence of somnolence with aripiprazole, however, was similar to that seen with placebo and lower than that seen with other active treatments. Objective rating scale assessments were used to assess changes in parkinsonian symptoms (Simpson-Angus Scale [SAS]), dyskinesias (Abnormal Involuntary Movement Scale [AIMS]), and akathisia (Barnes Akathisia Rating Scale [BAS]). SAS scores with aripiprazole did not differ significantly from those with placebo, whereas AIMS scores improved significantly from baseline with aripiprazole compared with placebo. Aripiprazole did not produce consistent dose-dependent changes in BAS scores. Haloperidol produced significant increases in SAS and BAS scores over placebo. Rates of discontinuation due to adverse events were similar among the groups: 9.4% with placebo, 8.0% with haloperidol, and 7.3% with aripiprazole (Otsuka Pharmaceutical 2006). According to the product labeling for aripiprazole in the United States, treatment-emergent adverse events reported with aripiprazole in short-term trials of patients with schizophrenia (up to 6 weeks) or bipolar disorder (up to 3 weeks) that occurred at an incidence greater than or equal to 10% and greater than placebo, respectively, included headache (30% vs. 25%), anxiety (20% vs. 17%), insomnia (19% vs. 14%), nausea (16% vs. 12%), vomiting (12% vs. 6%), dizziness (11% vs. 8%), constipation (11% vs. 7%), dyspepsia (10% vs. 8%), and akathisia (10% vs. 4%). A similar adverse-event profile was observed in a 26-week trial in schizophrenia except for a higher incidence of tremor (aripiprazole 8% vs. placebo 2%).

The most frequently reported adverse events with aripiprazole injection were headache (aripiprazole 12% vs. placebo 7%), nausea (aripiprazole 9% vs. placebo 3%), dizziness (aripiprazole 8% vs. placebo 5%), and somnolence (aripiprazole 7% vs. placebo 4%). In the three aripiprazole injection trials, the safety profile was comparable to that of placebo regarding the incidence of EPS, akathisia, or dystonia. The incidence of akathisia-related adverse events with aripiprazole injection was 2% (vs. 0% for placebo), while the incidence of dystonia with aripiprazole injection was less than 1% (vs. 0% for placebo). In addition, the incidence of QTc prolongation was also comparable between aripiprazole injection and placebo.

Weight gain is another adverse event of concern seen with some antipsychotic treatments, as it is associated with noncompliance (Allison et al. 1999), and excessive weight gain and obesity are linked to an increased risk of morbidity and mortality from heart disease, hypertension, and diabetes (Aronne 2001). Minimal changes in mean body weight were observed with aripiprazole treatment in short-term studies (pooled data, +0.71 kg) (Marder et al. 2003) and long-term studies (26-week: –1.26 kg; 52-week: +1.05 kg) (Kasper et al. 2003; Pigott et al. 2003).

Olanzapine and aripiprazole were compared on their propensity to cause weight gain and other metabolic disturbances in a 26-week randomized, double-blind multicenter trial in patients with DSM-IV schizophrenia who were in acute relapse and required hospitalization (McQuade et al. 2004). Significant weight gain was defined as more than 7% increase in body weight from baseline. Three hundred seventeen patients were randomly assigned to aripiprazole (n = 156) or olanzapine (n = 161). By week 26, 37% of olanzapine-treated patients had experienced significant weight gain, compared with 14% of aripiprazole-treated patients (P<.001). Statistically significant differences in mean weight change were observed between treatments beginning at week 1 and sustained throughout the study. At week 26, there was a mean weight loss of 1.37 kg (3.04 lb) with aripiprazole compared with a mean increase of 4.23 kg (9.40 lb) with olanzapine among patients who remained on therapy (P0.001). Changes in fasting plasma levels of total cholesterol, high-density lipoprotein cholesterol, and triglycerides were significantly different in the two treatment groups, with worsening of the lipid profile among patients treated with olanzapine.

Aripiprazole treatment was not associated with increases in prolactin levels during short- or long-term studies (in fact, prolactin levels were shown to be slightly decreased by aripiprazole). Patients receiving

aripiprazole treatment also showed decreases in mean QTc interval that were similar to those seen in patients who were receiving placebo in short-term studies (4.4 msec vs. 3.5 msec), as well as a low incidence of QTc increase ≥30 msec (aripiprazole: 4.3%; placebo: 5.5%). Aripiprazole was not associated with significant increases in QTc interval in long-term studies. Aripiprazole treatment was not associated with adverse changes in glucose or lipid levels during short- or long-term studies.

Overall, aripiprazole treatment is associated with a low incidence of EPS-related symptoms and with minimal or no effects on weight gain, QTc interval, or circulating levels of cholesterol, glucose, and prolactin. Treatment with aripiprazole may reduce the burden of antipsychotic-associated side effects, which is expected to improve patient adherence and reduce the risk of acute relapse.

DRUG–DRUG INTERACTIONS

Aripiprazole is metabolized primarily by the hepatic cytochrome P450 enzymes 2D6 and 3A4, so it has the potential to interact with other substrates for these enzymes. Inducers of these enzymes may increase clearance and so lower blood levels of aripiprazole, whereas inhibitors of 3A4 or 2D6 may inhibit elimination and so increase blood levels of aripiprazole. In vivo studies showed decreased levels of aripiprazole and dehydroaripiprazole in the plasma when aripiprazole was coadministered with carbamazepine, a cytochrome P450 3A4 inducer. The aripiprazole dose should therefore be increased when the drug is administered concomitantly with carbamazepine. In vivo studies coadministering aripiprazole and ketoconazole (a 3A4 inhibitor) or quinidine (a 2D6 inhibitor) suggest that the aripiprazole dose should be reduced when aripiprazole is administered with strong 3A4 or 2D6 inhibitors.

Aripiprazole is not a substrate for the cytochrome P450 enzymes 1A1, 1A2, 2A6, 2B6, 2C8, 2C9, 2C19, or 2E1 and so is unlikely to interact with inhibitors or inducers of these enzymes. Specific studies have demonstrated no clinically important interactions of aripiprazole with famotidine, valproate, lithium, dextromethorphan, warfarin, or omeprazole. Aripiprazole exhibits α_1-adrenergic receptor antagonist activity and so may enhance the effects of certain antihypertensive agents.

CONCLUSION

Aripiprazole is a novel antipsychotic agent that combines partial agonist activity at D_2 receptors with partial agonist activity at 5-HT_{1A} receptors and antagonist activity at 5-HT_{2A} receptors. This makes aripiprazole the first agent that is not a full D_2 antagonist to show rapid and sustained antipsychotic activity, and it may be considered the first partial DA agonist combined with 5-HT-stabilizing properties.

Short-term and long-term clinical trials in adult and pediatric patients with schizophrenia and bipolar I disorder have demonstrated that aripiprazole combines sustained antipsychotic and mood-stabilizing efficacy with an excellent safety and tolerability profile. Additional augmentation trials have confirmed the utility of aripiprazole in alleviating depressive symptomatology in patients with major depressive disorder who have not achieved adequate symptom relief with antidepressants alone. In general, aripiprazole treatment is associated with a low liability for EPS, QTc interval prolongation, prolactin elevation, weight gain, or disturbances of glucose or lipid metabolism. This combination of efficacy, safety, and tolerability suggests that aripiprazole has the potential to improve treatment adherence and decrease relapse rates and so represents an important new option for both acute and long-term treatment of schizophrenia and bipolar I disorder and as an adjunct to antidepressants in major depressive disorder.

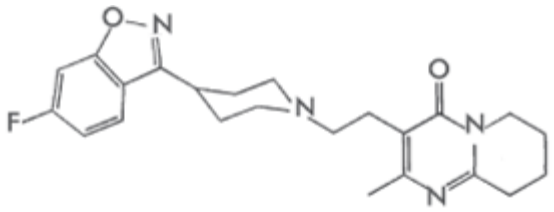
Chapter 32. Risperidone and Paliperidone

HISTORY AND DISCOVERY

A decade before clozapine was approved for marketing in the United States, Janssen Pharmaceuticals established a program to examine the potential role of serotonergic agents in schizophrenia. Early interest in serotonergic agents stemmed from a preclinical literature demonstrating that both behavioral effects of dopamine agonists and haloperidol-induced catalepsy could be modulated by serotonin$_2$ (5-HT$_2$) antagonists; in addition, the early butyrophenone derivative pipamperone, which was observed to reduce agitation and improve social activity in patients with severe depression, was found to possess primarily 5-HT$_2$ antagonist activity (Ansoms et al. 1977; Leysen et al. 1978).

In 1981, Janssen Pharmaceuticals developed setoperone, a 5-HT$_2$ antagonist with weak dopamine$_2$ (D$_2$) antagonism that displayed antipsychotic effects and efficacy for negative symptoms in a preliminary open trial (Ceulemans et al. 1985). Janssen Pharmaceuticals additionally synthesized a selective 5-HT$_{2A}$ and 5-HT$_{2C}$ antagonist, ritanserin, which was shown to decrease extrapyramidal side effects (EPS) when combined with haloperidol in rat studies. Ritanserin also was active in animal models of anxiety (Colpaert and Meert 1985; Meert and Colpaert 1986) and partially ameliorated behavioral effects of lysergic acid diethylamide (LSD) (Colpaert and Meert 1985). In placebo-controlled trials in patients with chronic schizophrenia, addition of ritanserin to conventional antipsychotics improved negative symptoms and EPS (Bersani et al. 1990; Duinkerke et al. 1993; Gelders 1989; Reyntjens et al. 1986). Concluding that 5-HT$_2$ antagonism might improve efficacy of D$_2$ blockers, particularly for negative symptoms, and reduce EPS, but that it was not sufficiently effective as monotherapy, Paul Janssen and colleagues undertook development of risperidone, which combined potent 5-HT$_{2A}$ and D$_2$ blockade.



After extensive preclinical characterization (Janssen et al. 1988), risperidone was first studied in clinical trials in 1986 and received U.S. Food and Drug Administration (FDA) approval for marketing in the United States in 1994. By the time risperidone became available to clinicians, the prominence of theories attributing 5-HT$_2$ enhancement of D$_2$ antagonism as a primary mechanism for clozapine's atypical properties (Meltzer et al. 1989), and the evidence from registration trials of reduced EPS and greater efficacy compared with high-dose haloperidol, resulted in considerable enthusiasm for the first of the "serotonin–dopamine antagonists." Risperidone was rapidly incorporated into clinical practice in the United States, where within 2 years it became the most frequently prescribed antipsychotic agent. In 2003, risperidone microspheres (Consta) received FDA approval as the first long-acting injectable second-generation antipsychotic. In December 2006, Janssen Pharmaceuticals introduced paliperidone (9-hydroxyrisperidone), the active metabolite of risperidone, formulated as an extended-release tablet marketed under the brand name Invega. A depot preparation, paliperidone palmitate, is currently in late-stage development.

PHARMACOLOGICAL PROFILE

Risperidone, or 3-[2-(4-[6-fluoro-1,2-benzisoxazol-3-yl]-1-piperidinyl)ethyl]-6,7,8,9-tetrahydro-2-methyl-4H-pyrido[1,2-a]pyrimidin-4-one, is a benzisoxazole derivative (Figure 32–1) characterized by very high affinity for 5-HT$_{2A}$ and moderately high affinity for D$_2$, H$_1$, and α_1- and α_2-adrenergic receptors. In vitro, the affinity of risperidone for 5-HT$_{2A}$ receptors is roughly 10- to 20-fold greater

than for D_2 receptors (Leysen et al. 1994; Schotte et al. 1996); in vivo binding to rat striatal D_2 receptors occurs at a dose 10 times higher than does binding to 5-HT_{2A} receptors (Leysen et al. 1994). The affinity for 5-HT_{2A} receptors is more than 100-fold greater than for other serotonin receptor subtypes. The active metabolite 9-hydroxyrisperidone has a similar receptor affinity profile. Both risperidone and 9-hydroxyrisperidone display high affinities for 5-HT_{2A} receptors in rat brain tissue and for cloned human receptors expressed in COS-7 cells (Leysen et al. 1994). Risperidone binds to 5-HT_{2A} receptors with approximately 20-fold greater affinity than clozapine and 170-fold greater affinity than haloperidol (Leysen et al. 1994).

The affinity of risperidone for D_2 receptors is approximately 50-fold greater than that of clozapine and approximately 20%–50% that of haloperidol (Leysen et al. 1994) (Table 32–1). Binding affinity for D_2 receptors was similar in rat mesolimbic and striatal tissue and in the long and short forms of cloned human D_2 receptors expressed in embryonic kidney cells (Leysen et al. 1993a). The affinities of risperidone and 9-hydroxyrisperidone for dopamine$_4$ (D_4) and D_1 receptors are similar to those of clozapine and haloperidol (Leysen et al. 1994). Risperidone has essentially no affinity for muscarinic acetylcholine receptors and modest histaminergic H_1 activity, whereas 9-hydroxyrisperidone minimally binds to H_1 receptors. Unlike haloperidol, risperidone does not bind to sigma sites (Leysen et al. 1994). However, compared with other agents, risperidone has a relatively high affinity for α_2-adrenergic receptors, which is substantially greater than that of clozapine or any conventional agent and which approaches the affinity of phentolamine (Richelson 1996). The affinity of risperidone for α_1-adrenergic receptors is roughly comparable to that of chlorpromazine and approximately 5 to 10 times greater than that of clozapine (Leysen et al. 1993b; Richelson 1996). The median effective dose (ED_{50}) of risperidone required to inhibit D_2-mediated apomorphine-induced stereotypies in rats is 0.5 mg/kg; at this dose, approximately 40% of D_2 receptors are occupied, as are 80% of 5-HT_{2A} receptors, 50% of H_1 receptors, 38% of α_1-adrenergic receptors, and 10% of α_2-adrenergic receptors (Leysen et al. 1994).

Several groups have studied the occupancy of D_2 and 5-HT_2 receptors in patients with schizophrenia, employing positron emission tomography (PET) or single-photon emission computed tomography (SPECT) ligand-binding techniques. Kapur et al. (1999) used PET to measure D_2 occupancy with ^{11}C-labeled raclopride and 5-HT_2 occupancy with ^{18}F-labeled setoperone in patients with chronic schizophrenia maintained on a stable clinician-determined dose of risperidone. The PET was performed 12–14 hours after the last dose of risperidone. Occupancy of D_2 receptors ranged from 63% to 89%; 50% occupancy was calculated to occur with a daily risperidone dose of 0.8 mg. Patients treated with risperidone (6 mg/day) exhibited a mean D_2 occupancy of 79%, which was consistent with the mean occupancy of 82% that was previously reported by Nyberg et al. (1999) and would be expected to exceed the putative threshold for EPS in some patients. A similar degree of D_2 occupancy was calculated to occur with olanzapine at approximately 30 mg daily (Kapur et al. 1999). A maximal 5-HT_2 occupancy of greater than 95% was achieved with risperidone at daily doses as low as 2–4 mg. In a small sample of patients treated biweekly for at least 10 weeks with risperidone microspheres (Consta), Remington et al. (2006) found that the 25-mg dose produced a mean D_2 occupancy of 54% (preinjection) and 71% (postinjection), whereas the 50-mg dose produced occupancy levels of 65% (preinjection) and 74% (postinjection).

Preclinical characterization of risperidone in rats revealed more potent antiserotonergic activity, compared with ritanserin, in all tests (Janssen et al. 1988). For example, in reversal of tryptophan-induced effects in rats, risperidone was 6.4 times more potent than ritanserin for reversal of peripheral 5-HT_2-mediated effects and 2.4 times more potent for reversal of centrally mediated 5-HT_2 effects (Janssen et al. 1988). Risperidone was also found to completely block discrimination of LSD, in contrast to the partial attenuation observed with ritanserin (Meert et al. 1989). Although risperidone demonstrated activity in all dopamine-mediated tests, the dose–response pattern differed from that of haloperidol (Janssen et al. 1988). The two drugs were roughly equipotent for inhibition of certain dopamine effects, such as amphetamine-induced oxygen hyperconsumption, whereas the dose of risperidone necessary to cause pronounced catalepsy in rats was 18-fold higher than that of haloperidol (Janssen et al. 1988). Risperidone depressed vertical and horizontal activity in rats at a dose 2–3 times greater than that of haloperidol but required doses more than 30 times greater than those of haloperidol to depress small motor movements (Megens et al. 1988).

PHARMACOKINETICS AND DISPOSITION

Risperidone is rapidly absorbed after oral administration, with peak plasma levels achieved within 1 hour (Heykants et al. 1994). In early Phase I studies, risperidone demonstrated linear pharmacokinetics at dosages between 0.5 and 25 mg/day (Mesotten et al. 1989; Roose et al. 1988). After a single dose of the extended-release formulation of paliperidone (Invega), serum concentrations gradually increase until a maximum concentration is achieved approximately 24 hours after ingestion. Absorption of paliperidone is increased by approximately 50% when taken with a meal compared with the fasted state. Extended-release paliperidone also demonstrates dose-proportional pharmacokinetics within the recommended dosing range (3–12 mg/day). Risperidone microspheres do not begin to release appreciable amounts of drug until 3 weeks after injection and continue to

release drug for approximately 4 weeks, with maximal drug release occurring after about 5 weeks. Risperidone is 90% plasma protein bound, whereas 9-hydroxyrisperidone (paliperidone) is 74% plasma protein bound (Borison 1994). The absolute bioavailability of risperidone is about 100%; that of extended-release paliperidone is about 28%.

Risperidone is metabolized by hydroxylation of the tetrahydropyridopyrimidinone ring at the seven and nine positions and by oxidative *N*-dealkylation (Mannens et al. 1993). The most important metabolite, 9-hydroxyrisperidone, accounts for up to 31% of the dose excreted in the urine and has a receptor affinity profile similar to that of the parent compound. Because hydroxylation of risperidone is catalyzed by cytochrome P450 (CYP) 2D6, the half-life of the parent compound varies according to the relative activity of this enzyme. In "extensive metabolizers," which include about 90% of Caucasians and as many as 99% of Asians, the half-life of risperidone is approximately 3 hours. In healthy subjects, approximately 60% of 9-hydroxyrisperidone is excreted unchanged in the urine, and the remainder is metabolized by at least four different pathways (dealkylation, hydroxylation, dehydrogenation, and benzisoxazole scission), none of which accounts for more than 10% of the total. The terminal half-life of 9-hydroxyrisperidone (and of extended-release paliperidone) is 23 hours. "Poor metabolizers" metabolize risperidone primarily via oxidative pathways; the half-life may exceed 20 hours. In extensive metabolizers, radioactivity from ^{14}C-labeled risperidone is not detectable in plasma 24 hours after a single dose, whereas 9-hydroxyrisperidone accounts for 70%–80% of radioactivity. In poor metabolizers, risperidone is primarily responsible for radioactivity after 24 hours. In the U.S. multicenter registration trial, the correlations between risperidone dose and serum risperidone and 9-hydroxyrisperidone concentrations were 0.59 and 0.88, respectively (Anderson et al. 1993).

MECHANISM OF ACTION

As previously discussed, risperidone was developed specifically to exploit the apparent pharmacological advantages of combining 5-HT_2 antagonism with D_2 blockade. Selective 5-HT_{2A} antagonists administered alone have demonstrated activity in several animal models suggestive of antipsychotic effect, including blockade of both amphetamine- and phencyclidine (PCP)–induced locomotor activity (Schmidt et al. 1995). Dizocilpine-induced disruption of prepulse inhibition is also blocked by 5-HT_{2A} antagonists, suggesting that sensory gating deficits characteristic of schizophrenia and perhaps resulting from glutamatergic dysregulation might also benefit from the 5-HT_2 antagonism of risperidone (Varty et al. 1999). The disruption of prepulse inhibition by dizocilpine (MK-801, a noncompetitive *N*-methyl-D-aspartate [NMDA] antagonist) is attenuated by atypical antipsychotics, but not by conventional D_2 blockers (Geyer et al. 1990). From a study in which the selective 5-HT_{2A} antagonist M100907 was added to low-dose raclopride (a selective D_2 blocker), Wadenberg et al. (1998) concluded that 5-HT_{2A} antagonism facilitates D_2 antagonist blockade of conditioned avoidance, another behavioral model associated with antipsychotic efficacy, but does not block conditioned avoidance when administered alone.

One mechanism by which risperidone, paliperidone, and similar atypical agents might produce enhanced efficacy for negative symptoms and cognitive deficits and reduced risk for EPS is via 5-HT_{2A} receptor modulation of dopamine neuronal firing and cortical dopamine release. Prefrontal dopaminergic hypoactivity has been postulated to underlie negative symptoms and cognitive deficits in schizophrenia (Goff and Evins 1998); both clozapine and ritanserin have been shown to increase dopamine release in prefrontal cortex, whereas haloperidol does not (Busatto and Kerwin 1997). Following 21 days of administration, risperidone, but not haloperidol, continued to increase dopamine turnover in the dorsal striatum and prefrontal cortex (Stathis et al. 1996). Ritanserin has been shown to enhance midbrain dopamine cell firing by blocking a tonic inhibitory serotonin input (Ugedo et al. 1989). Ritanserin also normalized ventral tegmental dopamine neuron firing patterns in rats after hypofrontality was induced by experimental cooling of the frontal cortex (Svensson et al. 1989).

Svensson et al. (1995) have performed a series of elegant studies examining the impact of atypical antipsychotics on ventral tegmental dopamine firing patterns disrupted by glutamatergic NMDA receptor antagonists. In healthy human subjects, administration of the NMDA antagonist ketamine is widely regarded as a promising model for several clinical aspects of schizophrenia, including psychosis, negative symptoms, and cognitive deficits (Goff and Coyle 2001; Krystal et al. 1994). In rats, administration of the NMDA channel blockers dizocilpine or PCP increased burst firing of ventral tegmental dopamine neurons predominately projecting to limbic structures but reduced firing of mesocortical tract dopamine neurons and disrupted firing patterns. Administration of ritanserin and clozapine preferentially enhanced firing of dopamine neurons with cortical projections, and when added to a D_2 blocker, ritanserin increased dopamine release in prefrontal cortex. In addition to modulating ventral tegmental dopamine neuron firing, risperidone also blocks 5-HT_2 receptors on inhibitory γ-aminobutyric acid (GABA)-ergic interneurons, which could also influence activity of cortical pyramidal neurons that are regulated by these local inhibitory circuits (Gellman and Aghajanian 1994).

In placebo-controlled clinical trials, 5-HT_2 antagonists have reduced antipsychotic-induced parkinsonism and akathisia (Duinkerke et al. 1993; Poyurovsky et al. 1999). This effect may reflect 5-HT_{2A} antagonist effects upon nigrostriatal dopamine release. When combined with haloperidol, selective 5-HT_2 antagonists increase dopamine metabolism in the striatum and prevent an increase in D_2 receptor density, thereby possibly reducing the effects of D_2 receptor blockade and dopamine supersensitivity (Saller et al. 1990). These agents do not affect dopamine metabolism in the absence of D_2 blockade.

The relative importance of 5-HT_2 antagonist activity in producing atypical characteristics is the subject of debate. As argued by Kapur and Seeman (2001) and Seeman (2002), most atypical antipsychotic agents have dissociation constants for the D_2 receptor that are larger than the dissociation constant of dopamine. This "loose binding" to the D_2 receptor may allow displacement by endogenous dopamine and may contribute to a reduced liability for EPS and hyperprolactinemia. Unique among atypical agents, risperidone is "tightly bound" to the D_2 receptor, with a dissociation constant smaller than that of dopamine (Seeman 2002). A model for atypical antipsychotic mechanisms that emphasizes D_2 dissociation constants would predict that the apparent atypicality of risperidone, compared with that of haloperidol, reflects the reduced D_2 occupancy achieved by more favorable dosing rather than the intrinsic pharmacological characteristics of risperidone. According to some binding data, a comparable clinical dosage of haloperidol would be approximately 4 mg/day, rather than 20 mg/day as used in the North American multicenter registration trial (Kapur et al. 1999). Consistent with this view, benefits of risperidone for negative symptoms and EPS were less apparent when compared with lower doses of haloperidol or with lower-potency conventional agents (see "Indications and Efficacy" section later in this chapter) than when compared with high-dose haloperidol (20 mg/day).

An additional mechanism possibly contributing to the enhanced efficacy of risperidone and paliperidone is their considerable α-adrenergic antagonism. In a placebo-controlled augmentation trial, Litman et al. (1996) demonstrated significant improvement in psychosis and negative symptoms with the α_2-adrenergic antagonist idazoxan when it was added to conventional antipsychotics. Idazoxan has been shown to increase dopamine levels in the rat medial prefrontal cortex (Hertel et al. 1999). In aged rats (Haapalinna et al. 2000) and in patients with frontal dementias (Coull et al. 1996), α_2-adrenergic blockers have also been reported to improve cognitive functioning. Svensson et al. (1995) found that prazosin, an α_1 antagonist, inhibited both behavioral activation and the increase in mesolimbic dopamine release produced by PCP or MK-801.

In summary, risperidone and paliperidone possess at least two mechanisms that may confer atypical characteristics. 5-HT_{2A} antagonism partially protects against D_2 antagonist–induced neurological side effects and may improve negative symptoms and cognitive functioning via modulation of mesocortical

dopamine activity. In addition, blockade of adrenoceptors may further increase prefrontal cortical activity and could enhance antipsychotic efficacy by modulation of mesolimbic dopamine activity. Unlike other atypical agents, risperidone and paliperidone do not differ from conventional agents in their dissociation constant for the D_2 receptor; this feature perhaps accounts for the risk of EPS at high doses, as well as their greater propensity to cause hyperprolactinemia.

INDICATIONS AND EFFICACY

Risperidone is approved by the FDA for the treatment of schizophrenia, bipolar mania, and irritability associated with autism. In August 2007, the indication for schizophrenia was extended to include adolescents ages 13–17 years, and the bipolar mania indication was extended to include children 10–17 years of age. Risperidone microspheres (Consta long-acting injection) and extended-release paliperidone (Invega) are approved for the treatment of schizophrenia.

Schizophrenia

Clinical Trial Results for Risperidone

In the two North American registration trials (Chouinard et al. 1993; Marder and Meibach 1994), a total of 513 patients with chronic schizophrenia were randomly assigned to an 8-week double-blind, fixed-dose, placebo-controlled comparison of risperidone (2, 6, 10, or 16 mg/day) or haloperidol (20 mg/day). Risperidone dosages of 6, 10, and 16 mg/day produced significantly greater reductions, as compared with haloperidol, in each of the five domains of the Positive and Negative Syndrome Scale (PANSS), derived by principal-components analysis (Marder et al. 1997), and significantly higher response rates, defined as a 20% reduction in the PANSS total score. Effect sizes representing the difference in change scores between risperidone (6 mg/day) and haloperidol, although statistically significant, were uniformly small by Cohen's classification system (Cohen 1988): negative symptoms 0.31; positive symptoms 0.26; disorganized thoughts 0.22; uncontrolled hostility/excitement 0.29; and anxiety/depression 0.30 (Table 32–2). Severity of EPS was greater with haloperidol than with risperidone; further statistical analysis suggested that differences in EPS rates did not significantly influence the differences in PANSS subscale ratings (Marder et al. 1997). In fact, risperidone (10 and 16 mg/day) produced improvements in negative symptoms equivalent to those seen with risperidone (6 mg/day), despite increased EPS at the higher dosages of risperidone.

When risperidone (1, 4, 8, 12, and 16 mg/day) was compared with haloperidol (10 mg/day) in a large

8-week European trial involving 1,362 subjects with schizophrenia (Peuskens 1995), PANSS subscale change scores indicated preferential response to daily risperidone doses of 4 and 8 mg. However, neither the risperidone group taken as a whole nor individual risperidone doses achieved significantly better outcomes than haloperidol (10 mg/day) on any measure except for EPS, suggesting that the degree of the clinical superiority of risperidone, compared with haloperidol, may be dependent on the dosing of the comparator.

In the National Institute of Mental Health–funded Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE; Stroup et al. 2003), 1,432 patients with chronic schizophrenia were randomly assigned to double-blind, flexibly dosed treatment for 18 months with risperidone, olanzapine, quetiapine, ziprasidone, or the conventional antipsychotic comparator perphenazine. Clinicians could adjust the dosage of each drug by prescribing 1–4 capsules daily; risperidone capsules contained 1.5 mg, and the mean daily dose administered in the study was 3.9 mg. Based on the primary outcome measure, time to all-cause discontinuation, risperidone was less effective than olanzapine (mean dosage = 20 mg/day) and comparable in effectiveness to perphenazine (mean dosage = 21 mg/day) and the other atypical agents (Lieberman et al. 2005). Although differences in rates of dropout due to intolerance did not reach statistical significance, risperidone consistently was the best-tolerated drug, particularly in subjects who had failed their first-assigned drug due to intolerance.

Whereas the superior efficacy of risperidone for acute symptom reduction, compared with haloperidol, is quite broad (but of relatively small magnitude) and may be determined in part by the haloperidol dose, efficacy for prevention of relapse appears to be of a substantially greater relative magnitude. For example, Csernansky et al. (2002) randomly assigned 365 patients with stable schizophrenia or schizoaffective disorder to clinician-determined flexible dosing with risperidone or haloperidol for a minimum of 1 year. Kaplan-Meier estimates of the risk of relapse at the end of the study were 34% with risperidone, compared with 60% with haloperidol, a highly significant difference ($P = 0.001$).

Several studies have indicated that risperidone may significantly enhance cognitive functioning, particularly verbal working memory, compared with haloperidol (Green et al. 1997). More recently, in a large double-blind, flexibly dosed 3-month trial in first-episode schizophrenia patients, risperidone (mean dosage = 3.2 mg/day) produced a modest, although statistically significant, improvement in the composite cognitive score compared with haloperidol (mean dosage = 2.9 mg/day) (Harvey et al. 2005). Another large double-blind trial examined cognitive effects in chronic schizophrenia patients treated for 52 weeks with risperidone (mean dosage = 5.2 mg/day), olanzapine (12.3 mg/day), and haloperidol (8.2 mg/day) (Keefe et al. 2006). No difference between treatments was found in improvement on the composite cognitive score, although risperidone and olanzapine were superior to haloperidol in a secondary analysis of completers (Keefe et al. 2006). No significant differences in cognitive effects were found among risperidone, perphenazine, or the other atypical antipsychotics in the CATIE (Keefe et al. 2007).

Risperidone has been found to be well tolerated and effective in subgroups of patients with schizophrenia, including first-episode patients and elderly patients. In a 4 month double-blind trial comparing risperidone (mean dosage = 3.9 mg/day) and olanzapine (mean dosage = 11.8 mg/day) in 112 first-episode patients, both treatments were well tolerated, with an overall completion rate of 72% (Robinson et al. 2006). Response rates did not differ significantly between risperidone (54%) and olanzapine (44%), although patients who responded to risperidone were significantly more likely to retain their response. Experience with patients with treatment-resistant schizophrenia has been less consistent. In the U.S. multicenter registration study, Marder and Meibach (1994) found that patients who were presumed to have failed to respond to conventional agents, on the basis of a history of hospitalization for at least 6 months prior to study entry, did not respond to haloperidol (20 mg/day) but did display significant response to risperidone (6 and 16 mg/day), compared with placebo. Wirshing et al. (1999) reported significant improvement with risperidone (6 mg/day),

compared with haloperidol (15 mg/day), during a 4 week fixed-dose trial in 67 patients with schizophrenia and histories of treatment resistance. However, the difference between treatments was lost during a subsequent 4 week flexible-dose phase in which the mean risperidone dosage was increased to 7.5 mg/day and the mean haloperidol dosage was increased to 19.4 mg/day. Bondolfi et al. (1998) reported comparable significant improvement with risperidone (mean dosage = 6.4 mg/day) and clozapine (mean dosage = 292 mg/day) in a randomized, double-blind trial involving 86 patients with schizophrenia described as resistant or intolerant to conventional antipsychotics by history. In a large open trial, risperidone produced significantly higher response rates than did haloperidol in 184 patients with histories of poor response (Bouchard et al. 2000). The relative superiority of risperidone over haloperidol steadily increased over time, reaching a maximum at the conclusion of the 12-month study. In contrast, Volavka et al. (2002) found no difference between high-dose risperidone (8–16 mg/day) and haloperidol (10–20 mg/day) in patients established by history to be treatment resistant to conventional antipsychotics. In the CATIE, risperidone was more effective than quetiapine but did not differ from olanzapine and ziprasidone in patients who discontinued their first-assigned atypical antipsychotic medication due to lack of efficacy (Stroup et al. 2006). In contrast, patients who discontinued perphenazine (for any reason) subsequently did better on quetiapine or olanzapine than they did on risperidone (Stroup et al. 2007).

Clinical Trial Results for Paliperidone

Extended-release paliperidone (Invega) at dosages of 6, 9, and 12 mg/day was more effective than placebo in a 6-week trial in acutely ill schizophrenia patients (Kane et al. 2007). In a flexibly dosed trial, extended-release paliperidone (9–15 mg/day) significantly reduced relapse compared with placebo (Kramer et al. 2007). The long-acting risperidone microsphere (Consta) formulation at fixed doses of 25 mg, 50 mg, and 75 mg administered biweekly was also superior in efficacy to placebo in a 12-week trial (Kane et al. 2003). In a 52-week study, treatment with risperidone microspheres was associated with low relapse rates; the incidence of relapse was 21.6% with the 25-mg dose and 14.9% with the 50-mg dose administered every 2 weeks (Simpson et al. 2006). In an open-label pilot trial of risperidone microspheres administered at a dose of 50 mg every 4 weeks, the 1-year relapse rate was estimated to be 22.4% (Gharabawi et al. 2007).

Affective Disorders

Six controlled trials of 3–4 weeks' duration that included a total of 1,343 patients have examined the efficacy of risperidone as monotherapy or in combination with a mood stabilizer for the acute treatment of bipolar mania (Rendell et al. 2006). As monotherapy and in combination, risperidone was more effective than placebo and comparable to haloperidol (Rendell et al. 2006). Risperidone's comparative efficacy in long-term prevention of relapse in bipolar disorder has not been established (Rendell and Geddes 2006).

Risperidone 1–2 mg/day was evaluated as an adjunct to antidepressant therapy in a 4-week placebo-controlled trial in 174 antidepressant-resistant patients with major depression recruited from 19 primary care and psychiatric centers (Mahmoud et al. 2007). Risperidone significantly lowered ratings of depressive symptoms compared with placebo. Remission rates were 25% with risperidone versus 11% with placebo (P = 0.004). Risperidone was well tolerated, with an 81% completion rate (vs. 88% with placebo).

Autism

Risperidone was also studied in a large 8-week placebo-controlled trial in 101 children (ages 5–17 years) with autism accompanied by severe tantrums, aggression, or self-injurious behavior (McCracken et al. 2002). Flexible dosing with risperidone (range = 0.5–3.5 mg/day; mean dosage = 1.2 mg/day) resulted in a mean reduction of 57% in irritability, compared with a decrease of 14% in the placebo group, and the response rate was 69% with risperidone versus 12% with placebo. In a

study of 32 children (ages 5–17 years) treated for 4 months with open-label risperidone (mean dosage = 2 mg/day), those who continued treatment with risperidone during the second study arm, an 8-week double-blind substitution trial, had much lower relapse rates than patients switched to placebo (Research Units on Pediatric Psychopharmacology Autism Network 2005). Risperidone at a mean dosage of 2 mg/day was also found to be effective compared with placebo in a study of 31 adults with autism or pervasive developmental disorder (McDougle et al. 1998). In these studies, risperidone improved irritability and behavioral problems associated with autism but was not effective for social or language deficits. Risperidone at a dosage of 0.02–0.06 mg/kg was found to be well tolerated and effective for disruptive behaviors in children with low intelligence (intelligence quotient [IQ] between 36 and 84) in a 6-week placebo-controlled trial (Aman et al. 2002).

Other Disorders

In a 4-week placebo-controlled trial in 417 patients with generalized anxiety disorder, anxiety symptoms improved to a similar degree in both the placebo and the risperidone groups (Pandina et al. 2007). Risperidone was highly effective for obsessive-compulsive disorder symptoms in a 6-week placebo-controlled trial in 36 adults prospectively confirmed to be refractory to treatment with a selective serotonin reuptake inhibitor (McDougle et al. 2000). Symptoms of anxiety and depression also responded to risperidone compared with placebo. Fifty percent of risperidone-treated patients responded (mean dosage = 2.2 mg/day), compared with 0% in the placebo group.

SIDE EFFECTS AND TOXICOLOGY

Risperidone shares class warnings with other atypical antipsychotics in the United States, including the risks of tardive dyskinesia, neuroleptic malignant syndrome, and hyperglycemia and diabetes, as well as the risk of increased mortality in elderly patients with dementia-related psychosis. However, risperidone generally has been very well tolerated in clinical trials. In the U.S. multicenter trial reported by Marder and Meibach (1994), only headache and dizziness were significantly more frequent with risperidone (6 mg/day), compared with placebo, whereas the group receiving risperidone (16 mg/day) treatment also reported more EPS and dyspepsia than did the group receiving placebo (Table 32–3). Fatigue, sedation, accommodation disturbances, orthostatic dizziness, palpitations or tachycardia, weight gain, diminished sexual desire, and erectile dysfunction displayed a statistically significant relationship to risperidone dose, although most were not significantly elevated compared with placebo. In a flexible-dose relapse prevention study reported by Csernansky et al. (2002), no side effects were more frequent with risperidone, compared with haloperidol, although risperidone produced significantly greater weight gain. In a flexibly dosed, placebo-controlled trial of risperidone for children with disruptive behavior, risperidone (mean dosage = 1.2 mg/day) produced more somnolence, headache, vomiting, dyspepsia, weight gain, and prolactin elevation than did placebo; most side effects were rated mild to moderate and did not adversely affect compliance (Aman et al. 2002).

Weight gain with risperidone is intermediate—that is, the degree of weight gain is between that associated with agents like molindone and ziprasidone, which appear to be relatively weight neutral, and that associated with agents like clozapine, olanzapine, and low-potency phenothiazines. In a meta-analysis of controlled trials, Allison et al. (1999), using a random effects model, estimated the mean weight gain at 10 weeks with risperidone to be 2.0 kg, compared with 0.5 kg with haloperidol, 3.5 kg with olanzapine, and 4.0 kg with clozapine. Although determining the risk for hyperglycemia is complex, and results of studies have not been completely consistent, it appears that risperidone does not produce insulin resistance and dyslipidemia to the degree associated with olanzapine and clozapine (American Diabetes Association et al. 2004; Henderson et al. 2006; Lieberman et al. 2005). In the CATIE, risperidone was associated with the lowest rate of discontinuation due to side effects (Lieberman et al. 2005). Risperidone treatment resulted in a mean 0.4-lb weight gain per month, compared with 2.0 lbs with olanzapine, 0.5 lb with quetiapine, and a mean monthly weight loss of 0.2 lb with perphenazine and 0.3 lb with ziprasidone.

Mesotten et al. (1989) reported the results of a safety trial involving 17 inpatients with psychosis in which, following a washout of previous medication, risperidone was started at 10 mg/day, and the dosage was then increased weekly by 5 mg/day to a maximum of 25 mg/day. Despite extremely high doses, sedation was the only prominent side effect. Although risperidone does not bind significantly to muscarinic cholinergic receptors, transient dry mouth, blurred vision, and urinary retention were observed in individual subjects. Palpitations occurred in 2 subjects. Heart rate significantly increased during the trial, and blood pressure slightly decreased; however; no cases of significant hypotension were reported. An endocrine battery, including plasma triiodothyronine, thyroid-stimulating hormone, growth hormone, prolactin, follicle-stimulating hormone, luteinizing hormone, and cortisol levels, was performed, and only prolactin was found to be affected.

Extrapyramidal Side Effects

Significant reductions in EPS with risperidone, compared with high-dose haloperidol, were a consistent finding in the North American trials (Chouinard et al. 1993; Marder and Meibach 1994). Measurement of EPS in the placebo group was complicated because 25% of the subjects were taking depot antipsychotics prior to enrollment. Risperidone produced significantly fewer parkinsonian side effects than did haloperidol (20 mg/day), based on several measures, including self-report, change scores on the Extrapyramidal Symptom Rating Scale (ESRS), and use of anticholinergic medication. Patients receiving risperidone (2 and 6 mg/day) did not differ from the group receiving placebo in mean ratings of parkinsonism and in the use of anticholinergic medication. Parkinsonism change scores were significantly correlated with the risperidone dosage ($r = 0.94$); however, risperidone (16 mg/day) was associated with fewer parkinsonian side effects than was haloperidol. Dystonia occurred in six of the patients treated with risperidone (1.7%) versus two of the patients treated with haloperidol (2.4%). Dystonia rates did not differ between treatment groups, and the rates did not exhibit a relationship to risperidone dosage.

In the large European multicenter trial, maximum ratings of parkinsonism, hyperkinesias, and dystonia were greater with haloperidol (10 mg/day) than with all dosages of risperidone (maximum of 12 mg/day), and anticholinergic dosing was accordingly higher in the group treated with haloperidol (Peuskens 1995). Similarly, in a flexible-dose comparison of risperidone (mean dosage = 4.9 mg/day) and haloperidol (mean dosage = 11.7 mg/day) for prevention of relapse, EPS rates and use of anticholinergic medication significantly favored the group taking risperidone (Csernansky et al. 2002). However, in a smaller double-blind, flexible-dose trial comparing risperidone (5–15 mg/day) and the moderate-potency conventional agent perphenazine (16–48 mg/day) in 107 patients, no difference in EPS rates was observed (Hoyberg et al. 1993), indicating that the potency of the comparator agent may in part determine the relative benefit of risperidone for EPS. Of interest, in a study of low-dose risperidone (mean dosage = 1.16 mg/day) in children with behavioral disorders, ratings of EPS did not differ between risperidone and placebo (Aman et al. 2002). No differences in EPS ratings were found between any treatment groups in the CATIE (Lieberman et al. 2005), although discontinuation rates due to EPS significantly differed, with perphenazine producing the highest discontinuation rate (8%) and olanzapine (2%), risperidone (3%), and quetiapine (3%) producing the lowest.

The experience with tardive dyskinesia (TD) in patients treated with risperidone has been quite promising. Jeste et al. (1999) randomly treated 122 elderly patients with low-dose haloperidol (median dose = 1 mg) versus risperidone (median dose = 1 mg). The very high rates of treatment-emergent TD typically found in geriatric patients make this sample a sensitive assay for TD risk. After 9 months, treatment-emergent TD rates were 30% with haloperidol versus less than 5% with risperidone. Risperidone was also noted to decrease dyskinetic movements, compared with haloperidol, in a Canadian multicenter trial reported by Chouinard et al. (1993), and it was associated with a treatment-emergent TD rate of 0.6%, compared with a rate of 2.7% with haloperidol, in a relapse prevention trial reported by Csernansky et al. (2002).

Hyperprolactinemia

Unlike other atypical antipsychotic agents, risperidone substantially increases serum prolactin levels—in some studies, to a greater degree than does haloperidol (Kearns et al. 2000; Markianos et al. 1999). The relationship between serum prolactin concentrations and clinical side effects remains somewhat unclear, however. Kleinberg et al. (1999) analyzed combined results from the North American and European multicenter registration trials, which included plasma prolactin concentrations from 841 patients and clinical ratings of symptoms associated with hyperprolactinemia from 1,884 patients. Mean prolactin levels significantly correlated with risperidone dosage; risperidone 6 mg/day produced elevations roughly comparable to those seen with haloperidol 20 mg/day and significantly higher than those seen with haloperidol 10 mg/day. The combined incidence of amenorrhea and

galactorrhea in women, which varied between 8% and 12%, was similar for all dosages of risperidone and haloperidol (10 mg/day). Because symptom frequencies were available only for 14 women treated with placebo, comparisons with placebo were not informative. Sexual dysfunction or gynecomastia occurred in 15% of men treated with risperidone (4–6 mg/day), compared with 14% of men treated with haloperidol (10 mg/day) and 8% of men in the placebo group. Compared with placebo, ejaculatory dysfunction was significantly more frequent only in the group treated with risperidone (12–16 mg/day). Mean plasma prolactin levels were not significantly related to clinical side effects for either men or women. Decreased libido also did not differ between treatment groups and did not correlate with plasma prolactin levels. In the CATIE, prolactin levels increased by a mean of 15.4 ng/mL with risperidone, compared with a 0.4-ng/mL mean elevation with perphenazine and decreases of 4.5–9.3 ng/mL with the other atypical agents (Lieberman et al. 2005). Despite having significantly higher serum prolactin concentrations, patients treated with risperidone did not report significantly higher rates of sexual dysfunction, gynecomastia, galactorrhea, or irregular menses.

Two reports of clinical trials with extended-release paliperidone have indicated low levels of prolactin-related side effects (1% and 4%) (Kane et al. 2007; Kramer et al. 2007). However, in the one publication that reported prolactin levels, substantial increases in mean plasma prolactin concentrations were observed (males: 17.4 ng/mL at baseline to 45.3 ng/mL at week 6; females: 38.0 ng/mL to 124.5 ng/mL) (Kane et al. 2007). Two preliminary studies with risperidone found that plasma prolactin concentrations correlated with 9-hydroxyrisperidone (paliperidone) concentrations and not with risperidone concentrations (Melkersson 2006; Troost et al. 2007). The ratio of 9-hydroxyrisperidone levels to risperidone levels also correlated with prolactin concentration (Troost et al. 2007); in agreement with this finding, rapid metabolizers of CYP2D6 were found to have higher prolactin concentrations than poor metabolizers (Troost et al. 2007). Because of the difficulty in establishing dose equivalence between risperidone and paliperidone in clinical trials, it is not clear whether the two drugs differ in their potential to elevate prolactin. Additional studies are needed to compare prolactin elevations with the two drugs.

Cardiovascular Effects

Because of relatively high affinities for adrenoreceptors, risperidone would be expected to produce orthostatic hypotension. However, by following a 3- to 7-day dosage escalation schedule, initial postural hypotension and tachycardia have been avoided in clinical trials, with only rare cases of hypotension and syncope reported (Chouinard et al. 1993; Marder and Meibach 1994). Risperidone has very modest effects on cardiac conduction. No significant prolongation of the QTc interval was detected at dosages of up to 25 mg/day in early safety trials, and no relationship between QTc interval and risperidone dose was apparent (Mesotten et al. 1989). In the CATIE, risperidone was associated with the least QTc prolongation (mean 0.2 msec) and quetiapine with the greatest (mean 5.9 msec), although differences were not statistically significant (Lieberman et al. 2005). A mean 10-msec prolongation of the QTc, measured after peak absorption of risperidone (16 mg/day), was found in a study comparing atypical and typical antipsychotic agents, according to data filed with the FDA by Pfizer Inc. (Harrigan et al. 2004). Reported overdoses with risperidone have generally been benign, with moderate QT prolongation and no serious cardiac complications (Brown et al. 1993; Lo Vecchio et al. 1996).

DRUG–DRUG INTERACTIONS

Because CYP2D6 status affects the half-life of risperidone and the relative ratio of risperidone to 9-hydroxyrisperidone in plasma, the total serum concentration of the "active moiety," or risperidone plus 9-hydroxyrisperidone, may be significantly increased with addition of a CYP2D6 inhibitor (e.g., fluoxetine) in rapid metabolizers but not in poor metabolizers (Bondolfi et al. 2002; Spina et al. 2002). Paliperidone plasma concentrations are not influenced by CYP2D6 status, nor are paliperidone plasma concentrations likely to be affected by drug–drug interactions. It is possible that the addition of a

CYP2D6 inhibitor (e.g., fluoxetine) could decrease risperidone-induced prolactin elevation by increasing the ratio of risperidone to 9-hydroxyrisperidone (Troost et al. 2007).

CONCLUSION

Risperidone was the first antipsychotic agent developed specifically to exploit the clinical advantages of combined D_2 and 5-HT_{A2} antagonism. α-Adrenergic antagonism additionally may contribute to the antipsychotic and cognitive-enhancing effects of risperidone. Risperidone is generally quite well tolerated, producing only moderate weight gain and mild sedation. Initial dosage titration is necessary to prevent orthostatic blood pressure changes and dizziness, although this may be less necessary with extended-release paliperidone. EPS are dose related, but their incidence at dosages less than or equal to 6 mg/day has not significantly differed from placebo. Risperidone substantially elevates prolactin levels, although the relationship between plasma prolactin concentrations and clinical symptoms is complex; prolactin-related side effects have not been detected in several studies of risperidone and paliperidone despite considerable prolactin elevation. The efficacy of risperidone is well established; compared with high-dose haloperidol, risperidone (6 mg/day) is significantly more effective for all five symptom clusters derived from the PANSS. Although it is broadly more effective, the magnitude of difference in effect size is not large for individual symptom clusters. At a dosage of 3.9 mg/day, risperidone did not differ from perphenazine in rates of discontinuation due to lack of effectiveness in the CATIE (Lieberman et al. 2005). Perhaps most impressive has been evidence indicating that risperidone is substantially more effective than haloperidol in preventing relapse. Evidence of enhanced cognitive functioning with risperidone, with particular benefits for verbal memory, is encouraging, although also of a relatively modest magnitude. The availability of risperidone microspheres (Consta), the first long-acting injectable atypical agent, represents an important advance with the potential both to improve compliance and to minimize peak serum drug concentrations associated with oral dosing. While extended-release paliperidone also produces more uniform serum concentrations and avoids the variability associated with CYP2D6 status, the possibility of greater prolactin elevation with this formulation requires further study.

Chapter 33. Ziprasidone

HISTORY AND DISCOVERY

Ziprasidone (CP-88059) is an atypical, or *second-generation*, antipsychotic agent that has demonstrated activity for treating positive, negative, cognitive, and affective symptoms of schizophrenia and schizoaffective disorder and for treating mania and mixed states in bipolar disorder, with limited adverse extrapyramidal, sedative, anticholinergic, and cardiometabolic effects. Ziprasidone was first synthesized on the Pfizer Central Research campus in Groton, Connecticut. Both the oral and intramuscular formulations of this antipsychotic were initially part of a new drug application for the treatment of psychotic disorders submitted to the U.S. Food and Drug Administration (FDA) under the product name Zeldox in 1997. Because of concerns regarding an observed increase in the mean duration of the QT interval, an electrocardiographic measure of the ventricular depolarization and repolarization phases of cardiac conduction, the application was not initially approved. Further studies, designed in collaboration with the FDA, quantified the limited extent of this effect seen with ziprasidone compared with the effect seen with other agents in wide use; these studies established an approvable level of safety for ziprasidone with respect to cardiac conduction and a benchmark for the approach to evaluating drug effects on the QT interval that has subsequently been applied to other agents evaluated by the FDA. The FDA approved oral ziprasidone in February 2001 under the trade name Geodon for the treatment of schizophrenia. The intramuscular formulation received FDA approval in 2002 for the treatment of acute agitation due to schizophrenia. In August 2004, oral ziprasidone received FDA approval for the treatment of bipolar mania, including manic and mixed episodes. At the time of writing, ziprasidone has received regulatory approval and is available in over 70 countries, usually under the trade name Zeldox, with more than 1.08 million patient-years of drug exposure.

PHARMACOLOGICAL PROFILE

Neuropharmacology and Receptor-Binding Profile

Ziprasidone, or 5-[2-[4-(1,2-benzisothiazol-3-yl)-1-piperazinyl]ethyl]-6-chloro-1,3-dihydro-2*H*-indol-2-one, is a novel benzisothiazolylpiperazine antipsychotic (Figure 33–1) with a unique structure and combination of receptor- and transporter-binding properties that distinguish it from other atypical/second-generation antipsychotics (Table 33–1) (Richelson and Souder 2000; Shapiro et al. 2003; Weiner et al. 2004).

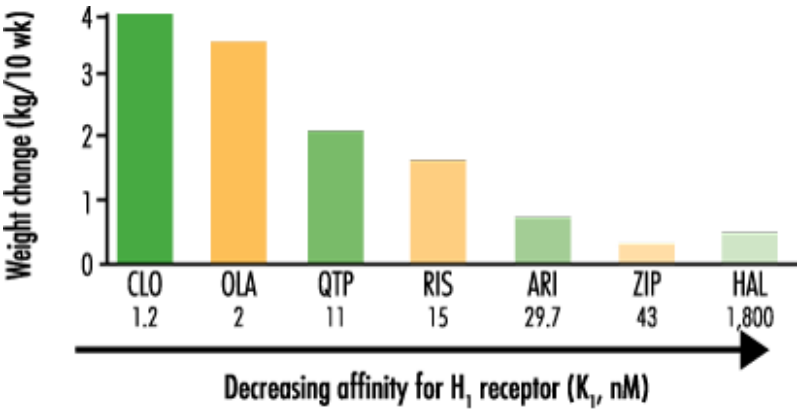
Ziprasidone is a potent antagonist at dopamine type 2 (D_2) receptors but possesses inverse agonist activity at 5-hydroxytryptamine (serotonin) type 2A receptors (5-HT_{2A} receptors). D_2 receptor antagonism is thought to be a key mechanism underlying efficacy for the treatment of psychotic symptoms (Kapur and Remington 2001); positron emission tomography (PET) studies have shown that clinical antipsychotic response to ziprasidone is predicted by occupancy of at least 60% of striatal D_2 receptors. D_2 antagonism is also associated with potential liability for extrapyramidal side effects (EPS). However, ziprasidone's inverse agonist activity at 5-HT_{2A} receptors disinhibits dopamine neurotransmission in the nigrostriatal, mesocortical, and tuberoinfundibular pathways (Kapur and Remington 1996; Schmidt et al. 2001); this reduces liability for EPS compared with antipsychotics with unopposed D_2 antagonism and potentially contributes to therapeutic effects. Increased dopamine activity in the prefrontal cortex is putatively linked to efficacy in improving the negative and cognitive symptoms of schizophrenia (Stahl and Shayegan 2003). Enhanced dopaminergic transmission in the tuberoinfundibular pathway minimizes the potential effect of D_2 receptor antagonism on prolactin



secretion. Ziprasidone's relatively high in vitro 5-HT_{2A}/D_2 receptor affinity ratio, compared with that of other second-generation antipsychotics, predicts both a low liability for EPS and potential therapeutic benefits for negative symptoms (Altar et al. 1986).

Ziprasidone exhibits antagonist activity at 5-HT_{1D} and 5-HT_{2C} receptors, and unique (among second-generation antipsychotics) agonist activity at 5-HT_{1A} receptors (see Table 33–1) (DeLeon et al. 2004; Schmidt et al. 2001). The 5-HT_{1A} affinity is comparable to that of buspirone, an agent with antidepressant and anxiolytic properties (Mazei et al. 2002), suggesting a mechanism that may contribute to observed beneficial effects on affective, cognitive, and negative symptoms in schizophrenia and schizoaffective disorder (Diaz-Mataix et al. 2005; Ichikawa et al. 2001; Millan 2000; Rollema et al. 2000; Sumiyoshi et al. 2003; Tauscher et al. 2002). Blockade of 5-HT_{2C} receptors disinhibits both dopamine and norepinephrine neurons in the cortex, an effect that could contribute to improvements in cognitive and affective abnormalities (Bremner et al. 2003; Bymaster et al. 2002; Mazei et al. 2002; Stahl 2003). Although 5-HT_{2C} antagonist activity is potentially predictive of weight gain liability, based, for example, on a 5-HT_{2C} knockout mouse model of obesity (Tecott et al. 1995), clinically significant predictive effects of 5-HT_{2C} antagonist activity on the weight gain risk associated with antipsychotic drugs have not been reliably detected (Kroeze et al. 2003), and the weight gain risk associated with ziprasidone is among the lowest of any currently available antipsychotic (Allison et al. 1999b). Potent antagonism at 5-HT_{1D} receptors has been proposed to potentially mediate antidepressant and anxiolytic effects (Briley and Moret 1993; Zorn et al. 1998).

Another unique feature of ziprasidone is its relatively high affinity for serotonin and norepinephrine transporters (Seeger et al. 1995; Tatsumi et al. 1999). In vitro, ziprasidone demonstrates dose-dependent reuptake inhibition of serotonin and norepinephrine transport, with effects ranging up to those of imipramine and amitriptyline (Schmidt et al. 2001), suggesting potential antidepressant activity. In vivo, the clinical significance of ziprasidone's monoaminergic reuptake inhibition may be limited by plasma protein binding or be clinically relevant only at higher than currently recommended daily dosages. Monoaminergic reuptake inhibition is associated with hippocampal neurogenesis, suggesting potential value in countering the neuronal cell loss observed in both affective illness and schizophrenia (Arango et al. 2001; Duman 2004; Thome et al. 1998). Relevant to this activity, treatment with ziprasidone and risperidone has been associated with an increase in cortical gray matter volume (Garver et al. 2005).

Ziprasidone has a low affinity for histaminergic$_1$ (H_1), muscarinic$_1$ (M_1), and α_1-noradrenergic receptors. Among the biogenic amine receptors, H_1 antagonist activity is the largest predictor of weight gain liability (Figure 33–2) (Kroeze et al. 2003). H_1 antagonist activity is also predictive of sedative effects, which are potentially undesirable for patients aiming to maximize cognitive performance and social, occupational, and community engagement. Low affinity for α_1-adrenergic receptors predicts a lower likelihood of orthostatic hypotension and sedation with ziprasidone than with commonly used antipsychotics with potent α_1-adrenergic antagonist activity. Low affinity for M_1 receptors predicts a low risk for anticholinergic side effects such as dry mouth, blurry vision, urinary retention, constipation, confusion, and memory impairment.

Ziprasidone's complex neuropharmacology provides explanatory support for observed treatment effects on psychotic and affective symptoms of schizophrenia, schizoaffective disorder, and bipolar disorder and for its favorable tolerability profile including minimal extrapyramidal and metabolic side effects (Stahl and Shayegan 2003).

Positron Emission Tomography Studies

An in vivo PET study (Mamo et al. 2004) examining the affinity of ziprasidone for dopamine (D_2) and serotonin (5-HT_2) receptors observed that optimal D_2 receptor occupancy occurs at the high end of the initially recommended dosage range. In this study, the ziprasidone plasma concentration associated with 50% of maximal D_2 receptor occupancy was more than twice the plasma concentration associated with 50% of maximal 5-HT_2 receptor occupancy. Using an imaging protocol where 60% or greater D_2 dopamine receptor occupancy is generally predictive of antipsychotic activity, approximately 60% D_2 occupancy was observed in relation to plasma concentrations equivalent to those attained with a dosage at or above 120 mg/day. These results, consistent with clinical trial results discussed later in this chapter (see "Indications and Efficacy"), strongly suggest that antipsychotic activity with ziprasidone is most commonly associated with dosages of 120 mg/day or greater (Figure 33–3).

Dosing Recommendations

In addition to the PET data, accumulating evidence from clinical trials (discussed below) suggests that ziprasidone dosing targets should be higher than initially recommended. In the United States, it was initially recommended that ziprasidone treatment in patients with schizophrenia be initiated at a dosage of 20 mg twice daily and then titrated at no less than 2-day intervals to a maximal dosage of 80 mg twice daily (Pfizer Inc. 2008). In contrast, more recent FDA approval of ziprasidone for the treatment of bipolar mania includes a recommendation that treatment be initiated at 40 mg twice daily with a more rapid titration; on the second day of treatment, the dosage should be increased to 60 or 80 mg twice daily and should subsequently be adjusted on the basis of toleration and efficacy within the 40- to 80-mg twice-daily range.

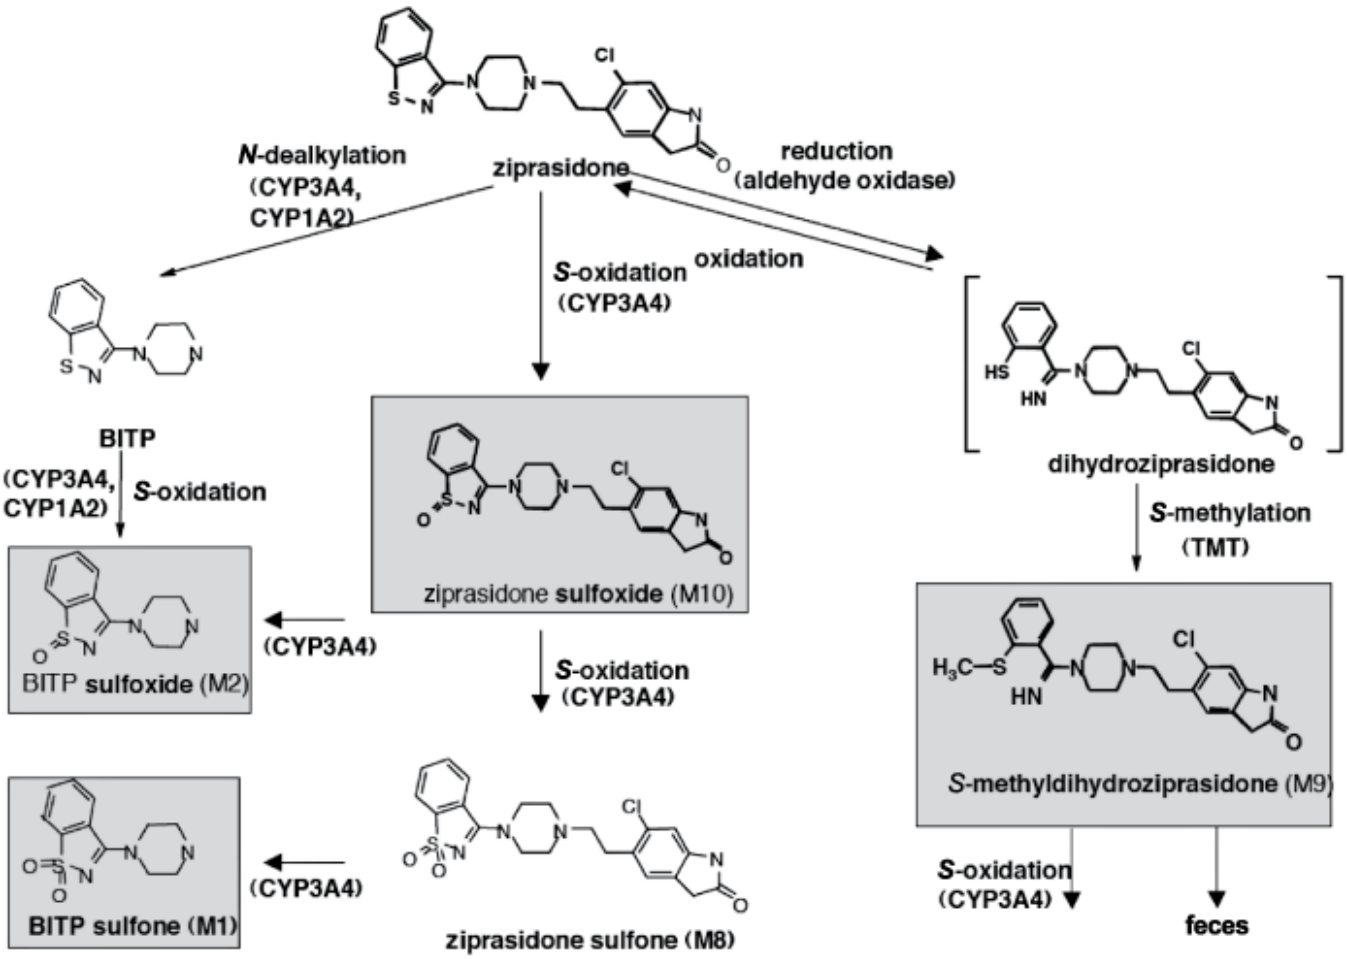
A review of short-term trials of ziprasidone (Kane 2003) concluded that daily dosages of 120–160 mg are more effective than lower dosages in the treatment of acute schizophrenia and also are associated with lower rates of medication discontinuation. A more recent 6-month prospective, observational, naturalistic, uncontrolled study performed in Spain also found that dosages greater than 120 mg/day were associated with a lower risk of discontinuation for any cause (Arango et al. 2007). As a corollary, another European observational multicenter trial found that both initial and overall underdosing are associated with high discontinuation rates (Kudla et al. 2007). In a pooled analysis of both flexible-dose and fixed-dose studies (*N* = 2,174), greater efficacy was observed in patients who received an initial dosage of 80 mg/day than in patients who received an initial dosage of 40 mg/day (Murray et al. 2004). Reported clinical experience with ziprasidone has also suggested the need for dosages greater than 160 mg/day in selected patients (Harvey and Bowie 2005; Nemeroff et al. 2005).

Finally, two large observational database analyses support the other lines of evidence suggesting that

higher dosages of ziprasidone are associated with better treatment outcomes than lower dosages (Joyce et al. 2006; Mullins et al. 2006). Both studies used prescription refills as an indicator of prescription adherence, a key measure of treatment continuation and overall effectiveness. Joyce et al. (2006) examined the files of more than 1,000 commercially insured patients with schizophrenia or schizoaffective disorder and concluded that an initial daily dosage of 120–160 mg was associated with a significantly lower risk of discontinuation at 6 months than an initial daily dosage of 60–80 mg. Mullins et al. (2006), evaluating a sample of more than 1,000 Medicaid recipients with schizophrenia, similarly concluded that patients receiving an initial dosage of 120–160 mg daily had lower rates of medication discontinuation than patients receiving an initial dosage of 20–60 mg daily. Taken together, results from receptor occupancy studies, clinical trials, and pharmacoepidemiological analyses provide support for the conclusion that initiation and treatment with ziprasidone dosages greater than 120 mg/day are more likely to be effective than lower dosages in the treatment of schizophrenia and schizoaffective disorder.

PHARMACOKINETICS AND DISPOSITION

Absorption and Distribution



Based on evidence of enhanced absorption in the presence of food, it is recommended that ziprasidone be taken with meals. Administration with food increases absorption by more than 50%, giving ziprasidone an oral bioavailability of approximately 60% (Pfizer Inc. 2008). Maximal plasma concentration (C_{max}) is achieved in 3.7–4.7 hours and reaches 45–139 µg/L in healthy volunteers receiving 20–60 mg twice daily, and steady-state serum concentrations occur within 1–3 days of twice-daily dosing (Hamelin et al. 1998; Miceli et al. 2000c). In contrast to oral administration, intramuscular administration of ziprasidone results in 100% bioavailability. A therapeutic plasma level is reached within 10 minutes, and C_{max} is achieved within 30 minutes of administration of a 20-mg dose (Pfizer Inc. 2008).

The mean apparent volume of distribution of ziprasidone is 1.5 L/kg (Pfizer Inc. 2008), which is lower than that of many other antipsychotic drugs. Given the wider potential for unwanted interactions with various intracellular targets that has been observed with lipophilic drugs having a high volume of distribution (Dwyer et al. 1999), this may be a favorable attribute for ziprasidone and other similar compounds. Ziprasidone is more than 99% bound to plasma proteins. However, in vitro binding studies indicate that it does not alter the protein binding of two highly protein-bound drugs, warfarin and propranolol, neither do these two drugs interfere with the protein binding of ziprasidone, suggesting that these types of drug interactions are unlikely.

Metabolism and Elimination

Ziprasidone is extensively metabolized with a mean terminal elimination half-life of approximately 7 hours after oral administration within the recommended clinical dosage range (Pfizer Inc. 2008). The elimination half-life of intramuscular ziprasidone is less than 3 hours with a single dose (Brook et al. 2000). Ziprasidone is cleared primarily via three metabolic pathways to yield four major circulating metabolites (Figure 33–4). Elimination occurs primarily through hepatic metabolism, with less than one-third of metabolic clearance mediated via cytochrome P450 (CYP)–catalyzed oxidation and approximately two-thirds via reduction of the parent compound by aldehyde oxidase to dihydroziprasidone, which then undergoes *S*-methylation. The current published literature reports no commonly encountered clinically significant pharmacological inhibitors of aldehyde oxidase, suggesting limited real-world potential for drug–drug interactions that would alter the clinical activity of ziprasidone (Obach et al. 2004).

Additional secondary metabolic pathways include *N*-dealkylation (via CYP enzymes 3A4 and 1A2) and direct *S*-oxidation (via CYP3A4) (Beedham et al. 2003; Prakash et al. 2000). *S*-methyl-dihydroziprasidone is the only active metabolite, with lower D_2 receptor affinity and no significant binding to H_1, M_1, or α_1- and α_2-adrenergic receptors. A small amount of the parent compound is excreted unchanged in the urine (<1%) and feces (<4%).

There are no clinically significant age- or gender-related differences in the pharmacokinetics of oral ziprasidone (Pfizer Inc. 2008). Hepatic impairment might be expected to increase the area under the time–concentration curve (AUC). A multiple-dose study (Everson et al. 2000) comparing subjects with clinically significant (Childs-Pugh Class A and B) cirrhosis versus healthy control subjects indicated that 12 hours after administration of ziprasidone, the AUC was 13% and 34% greater in subjects with Childs-Pugh Class A and B cirrhosis, respectively, than in matched control subjects, suggesting that dose adjustments are generally not mandatory for patients with hepatic impairment. Impairment in renal function is unlikely to significantly alter the pharmacokinetics of oral ziprasidone, suggesting that ziprasidone would not be removed by hemodialysis (Pfizer Inc. 2008). Intramuscular ziprasidone has not been systematically evaluated in the elderly or in patients with hepatic or renal impairment.

Intramuscular ziprasidone contains a cyclodextrin excipient that is cleared by renal filtration; thus, it should be administered with caution to patients with impaired renal function (Pfizer Inc. 2008).

Impact of Food on Pharmacokinetics

Recent pharmacokinetic studies examined ziprasidone bioavailability under fasting conditions and after eating food with varying caloric and fat composition to better understand effects of food intake on drug availability (Lombardo et al. 2007). In an open-label, nonrandomized, six-way crossover study, healthy adults received single doses of ziprasidone under fasting conditions and then under fed conditions with a standard meal of 800–1,000 calories. Serum ziprasidone levels were measured immediately prior to drug administration and at multiple scheduled time points up to 72 hours following drug administration. Ziprasidone exhibited linear pharmacokinetics in fed subjects, but nonlinear pharmacokinetics in fasting subjects. Dose-proportional increases in ziprasidone AUC and C_{max} were observed under fed but not fasting conditions. C_{max} was significantly higher in fed states than in fasting states at doses of 40 mg (63% higher) and 80 mg (97% higher). Results from two additional open-label crossover studies further clarified the factors regulating drug bioavailability (Lombardo et al. 2007). Results indicated that 1) significantly greater absorption is achieved during administration with a meal of at least 500 calories and 2) absorption is not significantly influenced by the fat content of the meal. These studies suggest that the administration of ziprasidone with food provides linear pharmacokinetics and optimal absorption, supporting predictable symptom control. In addition, the results suggest that total meal bulk sufficient to slow gastric and duodenal transit time (e.g., a bowl of oatmeal), rather than fat content or specific calorie counts, may be the key factor contributing to reliable dose-dependent drug absorption with meals.

DRUG–DRUG INTERACTIONS

A study of in vitro enzyme inhibition (Pfizer Inc. 2008) indicated that ziprasidone has little inhibitory effect on CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4 and is thus unlikely to interfere with the metabolism of other medications relying on these enzymes for clearance. In vivo studies indicated that ziprasidone has no effect on the pharmacokinetics of lithium, estrogen, progesterone, or dextromethorphan (Pfizer Inc. 2008). As noted above (in "Metabolism and Elimination" subsection), less than one-third of ziprasidone clearance is mediated by CYP-catalyzed oxidation and, based on this, one would not anticipate a substantial change in ziprasidone AUC during coadministration with CYP3A4 inhibitors or inducers. Aldehyde oxidase–mediated reduction of ziprasidone to its dihydro- metabolite constitutes the primary metabolic pathway for ziprasidone. As also noted above, currently no clinically significant pharmacological inhibitors of aldehyde oxidase are commonly encountered, which suggests that ziprasidone has limited potential for drug–drug interactions that would alter its clinical activity (Obach et al. 2004).

Consistent with this prediction, coadministration with ketoconazole, a potent CYP3A4 inhibitor, results in only a modest increase in ziprasidone AUC (33%) and C_{max} (34%) (Miceli et al. 2000b), while coadministration with carbamazepine, an inducer of 3A4, results in modest reductions in ziprasidone AUC (44%) and C_{max} (39%) (Miceli et al. 2000a). For comparison, a threefold increase in quetiapine C_{max} is observed during coadministration with ketoconazole, and a significant decrease in quetiapine C_{max} occurs during coadministration with CYP3A4 inducers (AstraZeneca 2008). Furthermore, coadministration with CYP2D6 inhibitors has no effect on ziprasidone plasma levels, whereas antipsychotics such as aripiprazole and risperidone exhibit a significant increase in plasma concentrations when coadministered with CYP2D6 inhibitors. Coadministration of ziprasidone with lithium results in no significant change, in steady-state lithium levels (Apseloff et al. 2000) and commonly used antacids and cimetidine do not significantly alter ziprasidone pharmacokinetics (Pfizer Inc. 2008).

INDICATIONS AND EFFICACY

Schizophrenia and Schizoaffective Disorder

Acute Treatment

Ziprasidone is indicated for the acute treatment of schizophrenia and schizoaffective disorder. Its efficacy in the treatment of hospitalized patients with acute schizophrenia or schizoaffective disorder has been demonstrated in a series of double-blind, placebo-controlled trials of 4–6 weeks' duration (Daniel et al. 1999; Kane 2003; P. Keck et al. 1998; P. E. Keck et al. 2001). Additional randomized, double-blind, short-term (4- to 8-week) treatment studies using active antipsychotic agent comparators have indicated that ziprasidone has efficacy comparable to that of haloperidol, risperidone, and olanzapine for the treatment of positive symptoms and overall psychopathology (Addington et al. 2004; Goff et al. 1998; Simpson et al. 2004a). In a pooled analysis of four placebo-controlled, short-term trials and three active-comparator trials, Murray et al. (2004) demonstrated that ziprasidone dosages of at least 120 mg/day, in comparison with lower dosages, are associated with a more rapid and favorable response in overall psychopathology as well as a lower discontinuation rate due to inadequate clinical response, suggesting the importance of rapid titration to at least 120 mg/day in patients with acute schizophrenia (Kane 2003; McCue et al. 2006).

Suboptimal dosing, titration, and administration of ziprasidone may have negatively impacted its performance in some clinical trials. Some clinical trials included efficacy data for dosages that would now be consider suboptimal (i.e., <120 mg/day), while other studies used prolonged titration of ziprasidone, only reaching a therapeutic dosage 1 week or more into the study. Clinical trials conducted before the release of the recent pharmacokinetic data by Lombardo et al. (2007) may not have been designed to ensure that ziprasidone was administered with food for optimal oral absorption. For example, one small randomized, open-label trial (*N* = 327) by McCue et al. (2006) compared the effectiveness of haloperidol, aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone for a minimum of 3 weeks as measured by duration of inpatient hospitalization. Although all six antipsychotics demonstrated comparable changes in Brief Psychiatric Rating Scale (BPRS) scores, treatment with haloperidol, olanzapine, and risperidone was associated with shorter hospital stays than treatment with aripiprazole, quetiapine, and ziprasidone. This study used slow, gradual titration of ziprasidone, so many patients did not obtain an optimal dosage of ziprasidone (e.g., 80 mg twice daily) until 1 week or more into this short-term study, suggesting an explanation for the longer duration of hospitalization in ziprasidone recipients despite achieving comparable improvement in BPRS scores.

Another approach to evaluating the comparative efficacy of first- and second-generation antipsychotics is the use of meta-analysis. A series of meta-analyses has found no clear or consistent differences among the atypical antipsychotics, either when comparing agents within the same class or when comparing second-generation with first-generation antipsychotics (Bagnall et al. 2003; Geddes et al. 2000; Leucht et al. 1999; Srisurapanont and Maneeton 1999; Tandon and Fleischhacker 2005). One meta-analysis of randomized, controlled trials by Davis et al. (2003) suggested that some atypical antipsychotics (i.e., clozapine, risperidone, olanzapine, and amisulpride) were significantly more efficacious than first-generation antipsychotics, whereas in this analysis the efficacy of ziprasidone was not observed to be statistically significantly better than that of first-generation antipsychotics. It is important to note that this meta-analysis excluded data relating to low dosages of other antipsychotics (olanzapine <11 mg/day and risperidone <4 mg/day), but included data on ziprasidone dosages as low as 80 mg/day. In addition, the Davis et al. meta-analysis included relatively few studies of ziprasidone (4 studies as compared with 31 studies of clozapine, 22 studies of risperidone, and 14 studies of olanzapine), making it more difficult to show statistical significance with this agent. In a subsequent analysis of data from four major meta-analyses plus additional data from head-to-head comparisons of agents in randomized, controlled clinical trials, Tandon and Fleischhacker (2005) found that all of the second-generation antipsychotics including ziprasidone were statistically equivalent in terms of efficacy.

It should be noted that meta-analyses involving ziprasidone are challenged by the same limitations incurred by the original study designs. These early study limitations included problems related to inadequate dosing and/or dose titration and administration without food. Although meta-analyses provide useful information, a need remains for head-to-head comparator studies with flexible doses and appropriate dosage ranges to address whether specific antipsychotic drugs exhibit preferential

benefit–risk ratios in relevant patient populations.

Debate continues about potential explanations for why some studies find differences in acute efficacy among the second-generation antipsychotics and other studies do not, with limited evidence suggesting that study sponsorship might occasionally contribute to a biased study design (e.g., sponsors might design a study using suboptimal dosing or titration of a comparator) (Lexchin et al. 2003). Based on the totality of available evidence, it is our opinion that there is currently no compelling overall evidence to support propositions that clinically significant differences (i.e., differences that are not explainable by lack of equipotent dosing with respect to D_2 antagonist activity) exist in the intrinsic efficacy of second-generation antipsychotics for the treatment of positive psychotic symptoms in patients with schizophrenia or schizoaffective disorder, with the exception of the superior efficacy for positive symptoms of clozapine in well-defined populations of patients with treatment-resistant illness.

With respect to drug effects on total psychopathology, beyond specific effects for positive symptoms, it is important to note that in general, when the less sedating antipsychotics compete in head-to-head comparisons with more sedating agents, they tend to face challenges in conventionally designed randomized, double-blind trials. When the acute state under study also involves agitation and insomnia, less sedating medications (e.g., ziprasidone) may be at a disadvantage with respect to ratings for these additional symptoms. Although conventional study designs allow "as needed" access to adjunctive benzodiazepines, the as-needed approach carries a potential for underutilization that may fail to fully level the playing field with respect to sedative effects in the competing treatment arms. Conventional study designs will continue to present challenges for the growing list of novel antipsychotic agents under development that, like ziprasidone, are at the less sedating end of the spectrum of currently available agents. The key question is whether it is desirable to continue to rely on study designs that favor more sedating agents, given that this will tend to favor agents with higher levels of intrinsic antihistaminic, antimuscarinic, or anti–α_1-adrenergic activity, encouraging the development of medications with predictable short- and longer-term adverse-event liabilities.

Maintenance Therapy

The maintenance efficacy of ziprasidone in treating schizophrenia and schizoaffective disorder has been studied in a series of double-blind and open-label extension trials (Arato et al. 2002; Hirsch et al. 2002; Kane et al. 2003; Schooler 2003; Simpson et al. 2002, 2004b). These studies indicate that long-term therapy with ziprasidone maintains clinical response and is effective in preventing relapse. The majority of efficacy and effectiveness studies for ziprasidone can be divided into specific categories based on what the studies were designed to assess:

1. Maintenance of effect: patients who meet acute response criteria are randomized to stay on the current medication or switch to a comparator treatment
2. Relapse prevention: stable patients defined in terms of remission or level of symptom control are randomly assigned to ziprasidone versus a control condition and are compared by time to achievement of relapse criteria
3. Long-term response: symptomatic patients are compared by improvements in clinical symptom response
4. Clinical effectiveness: so-called effectiveness trials use endpoints such as time to drug discontinuation as a marker for clinical effectiveness

Maintenance of effect

In two maintenance-of-effect trials, patients with schizophrenia or schizoaffective disorder with a demonstrated acute response to treatment (defined as a ≥20% decrease in Positive and Negative Syndrome Scale [PANSS] for schizophrenia total score and a Clinical Global Impression [CGI] Scale score of ≤2) were randomly assigned to receive either ziprasidone or a comparator antipsychotic agent for at least 26 weeks (Addington et al. 2003; Schooler 2003; Simpson et al. 2002, 2005). The ziprasidone treatment groups in both studies demonstrated significant improvements from baseline in overall psychopathology, as measured by mean changes in symptom ratings using PANSS total, PANSS negative subscale, Brief Psychiatric Rating Scale–Depression Factor (BPRSd), and CGI–Severity (CGI-S) scores.

These improvements were comparable to those seen in the olanzapine (Simpson et al. 2005) and risperidone (Addington et al. 2003) treatment groups.

Relapse prevention

To evaluate the efficacy of ziprasidone for relapse prevention, the Ziprasidone Extended Use in Schizophrenia study enrolled stable inpatients with chronic schizophrenia and randomly assigned participants to 1 year of treatment with ziprasidone 40 mg/day (*n* = 72), 80 mg/day (*n* = 68), or 160 mg/day (*n* = 67) or placebo (*n* = 71), with a planned primary Kaplan-Meier analysis of time to relapse (Arato et al. 2002). Stability was defined by symptom level but this was short of strict definitions of remission. In this study, all three dosages of ziprasidone were superior to placebo in the prevention of relapse. In addition, a penultimate-observation-carried-forward analysis (in which the last visit prior to relapse is excluded) was performed to filter out clinical worsening associated with relapse that might otherwise obscure symptom response trends during the rest of maintenance therapy (O'Connor and Schooler 2003), which indicated that nonrelapsing patients treated with ziprasidone experienced modest symptomatic improvement during maintenance treatment. This study, like a number of other studies of other antipsychotic agents in schizophrenia patients, was limited by the relatively high level of attrition observed in all groups over the year of treatment.

Long-term response to treatment in symptomatic patients

A number of long-term double-blind trials designed to examine the efficacy of ziprasidone in symptomatic patients with schizophrenia have been performed (Breier et al. 2005; Hirsch et al. 2002; Kinon et al. 2006a; Simpson et al. 2004a, 2005). Investigators (Hirsch et al. 2002) have compared the efficacy of ziprasidone (*n* = 148) and haloperidol (*n* = 153) in a 28-week double-blind trial of stable outpatients with schizophrenia with prominent negative symptoms. In this study, ziprasidone and haloperidol were similarly efficacious in reducing overall psychopathology, with an advantage for ziprasidone in the percentage of patients classified as negative symptom responders. Breier et al. (2005) conducted a 28-week study of ziprasidone and olanzapine in outpatients as well as inpatients (*N* = 548) with active symptoms. In this study, olanzapine treatment was associated with greater improvement from baseline in total psychopathology scores (PANSS total, the primary efficacy measure) than ziprasidone and a higher rate of criterion-level response to treatment. Simpson et al. (2004a) conducted a 6-week double-blind, parallel-design flexible-dose comparison (*N* = 269) of ziprasidone (*n* = 136) and olanzapine (*n* = 133) where at least minimal responders (CGI-I score ≤2 or ≥20 % reduction in PANSS total score) were enrolled in a 6-month double-blind continuation trial (Simpson et al. 2005). In both the 6-week and the 6-month analyses, no differences between the treatment groups were detected on any primary (e.g., BPRS total, CGI severity) or secondary (e.g., PANSS total, CGI-I) measures.

Factors contributing to the apparent differences in study results may include differences in study design. Breier et al. (2005) randomly assigned symptomatic inpatients and outpatients, whereas Simpson et al. (2004a) enrolled symptomatic inpatients at baseline for the 6-week trial and patients with at least minimal response into the subsequent 6-month trial. Breier et al. (2005) used a higher mean daily dosage of olanzapine (15.3 mg) and a lower mean daily dosage of ziprasidone (116.0 mg) in comparison with the Simpson et al. (2004a, 2005) studies, which used relatively lower mean daily dosages of olanzapine (11.3 mg and 12.6 mg, respectively) and relatively higher mean daily dosages of ziprasidone (129.9 mg and 135.2 mg, respectively). Breier et al. (2005) also employed a prolonged titration of ziprasidone, along with the lower dosage, increasing the likelihood of initial and sustained underdosing of ziprasidone.

In another comparison study of ziprasidone and olanzapine, Kinon et al. (2006a) evaluated their efficacy in schizophrenia and schizoaffective disorder patients with prominent depressive symptoms (*N* = 394). They detected greater improvement in PANSS total scores in the olanzapine group, using a last-observation-carried-forward analysis. However, no significant difference in PANSS total scores between olanzapine and ziprasidone treatment was detected using an alternative mixed-effects model for repeated measures (MMRM) analysis. The MMRM analysis notably uses all observed data to adjust for changes related to dropouts and may offer a more robust approach to the analysis of treatment effects in

clinical trials when missing data occur (Mallinckrodt et al. 2003).

Effectiveness trials

There have been a number of ziprasidone effectiveness trials, with use of various definitions for *effectiveness.* The Clinical Antipsychotic Trials of Intervention Effectiveness (the CATIE studies, funded by the National Institute of Mental Health [NIMH]) included a long-term, double-blind, randomized study of patients with schizophrenia (*N* = 1,493; Lieberman et al. 2005). Phase I of the CATIE schizophrenia study compared ziprasidone, olanzapine, quetiapine, risperidone, and perphenazine on the primary endpoint of time to discontinuation for lack of efficacy or for any cause. Because of the timing of its FDA approval, ziprasidone was added to the study after enrollment had begun for all other treatment arms; this resulted in a smaller sample size for the ziprasidone treatment arm.

The primary analysis for the phase I study detected significant differences in time to discontinuation across the treatment groups overall. The longest time to discontinuation was in the olanzapine group. In the total study sample, no significant differences were seen in the time to discontinuation between the ziprasidone and olanzapine treatment groups, nor between the ziprasidone group and other antipsychotic treatment groups. Although a subanalysis that was restricted to the overall study cohort of patients who enrolled after ziprasidone became available indicated a higher rate of discontinuation with ziprasidone treatment than with olanzapine, this was not significant after a planned adjustment for multiple comparisons. After adjusting the data for multiple comparisons, the investigators found no significant differences between ziprasidone and olanzapine or the other antipsychotics in the analyses of all-cause discontinuations and discontinuations due to lack of efficacy.

Several considerations in this complex study are worth mentioning. Relatively few patients who entered the CATIE schizophrenia study were currently (i.e., prior to study entry) taking the relatively newly available medication, ziprasidone, compared with the number of patients taking the other antipsychotic medications in the trial. This resulted in a larger proportion of patients assigned to the ziprasidone treatment arm who were just starting to take a new medication and discontinuing their prior treatment, compared with patients in other treatment arms. For example, 23% of subjects randomly assigned to olanzapine treatment were already receiving olanzapine monotherapy as their ongoing treatment, requiring no medication discontinuation or new drug initiation as a result of their random assignment to the study arm. Supplemental analysis of phase I CATIE data by Essock et al. (2006) indicated the overall importance, in terms of subsequent discontinuation rates, of whether randomized subjects were switching medications or whether the study design allowed them to continue receiving their prior treatment. A significantly higher rate of subsequent discontinuation was observed in patients who actually made a medication switch compared with those who were randomly assigned to stay with the same medication they had been taking prior to the trial. This effect of switching medications may therefore favor treatment arms with a larger percentage of "nonswitchers" (i.e., olanzapine and risperidone recipients in the CATIE phase I study, in which nonswitching was allowed). In a reanalysis of phase I CATIE data that excluded those patients randomly assigned to continue taking the antipsychotic that they were already taking at baseline, Essock et al. (2006) found that differences between rates of discontinuation in the ziprasidone group and rates in the other antipsychotic groups were attenuated, and no statistically significant differences were observed.

Further evidence regarding the effectiveness of ziprasidone was anticipated from the phase II CATIE study. Subjects enrolled in the phase I study consisted of a population that included some patients with unremitted illness and some patients with treatment-refractory illness (Meltzer and Bobo 2006), not undesirably increasing the likelihood that subjects would discontinue treatment in phase I and move on to phase II of the CATIE study. However, the CATIE study hypothesized that patients who discontinued phase I due to lack of efficacy would tend to enter the phase IIE *efficacy arm,* which included clozapine, while those who discontinued phase I due to intolerability would tend to enter the phase IIT *tolerability arm,* which included ziprasidone (Stroup et al. 2006). Instead, a substantial percentage of patients who discontinued phase I due to lack of efficacy chose not to enter the IIE arm of the study, possibly due to

reluctance to receive treatment with clozapine, and instead entered the IIT arm. From this larger-than-expected sample of phase IIT subjects, those randomly assigned to the ziprasidone group received a mean modal dosage of 116 mg/day, with only about one-third of those treated receiving the maximal allowed dosage of 160 mg/day and about 60% receiving 120 mg/day or less, and there were no study-specified requirements or instructions regarding administration of the drug with food. In this setting, ziprasidone, like quetiapine, was associated with a shorter time to all-cause discontinuation of treatment than risperidone or olanzapine. In the subset of the sample that entered phase II due to lack of tolerability in phase I (rather than lack of efficacy), no differences in all-cause discontinuation rates were observed between the treatment arms.

The ZEISIG study (Ziprasidone Experience in Schizophrenia in Germany/Austria) investigated the effectiveness of ziprasidone as measured by discontinuation rates and mean changes of the BPRS total in moderately ill and reasonably stable patients (*N* = 276) with schizophrenia or schizoaffective disorder (Kudla et al. 2007). Approximately 60% of subjects discontinued ziprasidone prematurely, most within the first 4 weeks of study treatment. In study completers, ziprasidone was associated with significant improvements in BPRS total score. The relatively high rate of discontinuation may be explained in part by the planned dosing strategy. In this study, ziprasidone use was initiated at a low dosage of 40 mg/day, which is now known to be associated with higher discontinuation rates and shorter durations of therapy compared with higher dosages (Joyce et al. 2006; Mullins et al. 2006). As in other studies, the maximal dosage allowed was 160 mg/day, which may be insufficient for some patients (Harvey and Bowie 2005; Nemeroff et al. 2005).

Arango et al. (2007), of the Ziprasidone in Spain Study Group, examined the effectiveness of ziprasidone (*n* = 1,022 in the primary analysis sample) as measured by response rate (defined as a ≥30% reduction in the PANSS total score). Nearly half of the patients experienced the defined level of clinical response, and patients overall had significant and clinically relevant mean reductions in both the PANSS total score and the positive, negative, and general psychopathology subscale scores (effect sizes were 1.60, 1.83, 0.62, and 1.40, respectively). Ziprasidone dosages of greater than 120 mg/day were associated with a lower risk of discontinuation for any cause.

Kinon et al. (2006b) published a post hoc pooled analysis of clinical trials from the Eli Lilly database using treatment discontinuation rates as a measure of effectiveness. An additional long-term effectiveness study (Ascher-Svanum et al. 2006) using time to all-cause discontinuation as a measure of effectiveness, and a naturalistic treatment setting, is available. In both cases, small numbers of subjects in the ziprasidone arms (e.g., 25 subjects), compared with hundreds or more subjects in comparative arms, limit the interpretation of results and conclusions with respect to ziprasidone.

Efficacy by Symptom Type

Efficacy for cognitive symptoms of schizophrenia

The effect of ziprasidone on cognitive function in schizophrenia patients has been evaluated by a battery of cognitive tests that were included in a double-blind olanzapine comparator study that evaluated changes at 6 weeks and 6 months (Harvey et al. 2004, 2006a). Antipsychotic treatment with ziprasidone and with olanzapine both resulted in significant cognitive improvements from baseline in attention memory, working memory, motor speed, and executive functions, with olanzapine also associated with improvement in verbal fluency. Further improvements in both treatment groups were observed from the end of 6 weeks to the 6-month assessment time point on verbal learning, executive functioning, and verbal fluency, with no differences between treatment groups. A similar magnitude of improvement was seen with each agent, with the exception of verbal fluency. It should be noted that despite improvements, a substantial proportion of patients studied continued to experience clinically significant cognitive impairment posttreatment. Neuropsychological improvements in general are not related to clinical changes (Harvey et al. 2006b).

Recent data from the CATIE schizophrenia study indicate that treatment with all of the antipsychotics

tested (i.e., ziprasidone, perphenazine, olanzapine, risperidone, and quetiapine) was associated with a small but significant improvement in neurocognition after 2 months of treatment (Keefe et al. 2007). There was no significant difference between ziprasidone and the other antipsychotics. Neurocognitive improvement predicted a longer time to treatment discontinuation, independent of symptom improvement, in patients treated with quetiapine or ziprasidone.

Efficacy for affective symptoms

Ziprasidone has been hypothesized to be a promising treatment for affective disorders, based on its unique in vitro potency as a serotonin and norepinephrine reuptake inhibitor comparable to that of known antidepressants (see "Neuropharmacology and Receptor-Binding Profile" section above). If this effect translates to antidepressant activity in vivo, it could be useful in reducing the likelihood of treatment-emergent depression, an outcome in approximately 10%–20% of patients with bipolar or schizoaffective disorder treated with first-generation antipsychotics or olanzapine (Kohler and Lallart 2002; Tohen et al. 2000, 2001, 2003). Addressing the question of ziprasidone's potential antidepressant efficacy in schizophrenia patients with comorbid affective symptoms, data can be examined from randomized, double-blind, placebo-controlled clinical trials (Daniel et al. 1999; P. Keck et al. 1998; P. E. Keck et al. 2001) and from double-blind, head-to-head trials comparing ziprasidone to risperidone or olanzapine (Kane 2003). The results of placebo-controlled studies (Daniel et al. 1999; P. Keck et al. 1998) suggest that treatment of schizophrenia and schizoaffective disorder with ziprasidone is associated with significant improvement in comorbid depressive symptoms, based on intent-to-treat analyses, but sometimes only in the subset of patients with higher levels of baseline depression. The baseline severity of depressive symptoms in these studies tends to be relatively mild, so subgroups of patients with more pronounced comorbid depressive symptoms at baseline were also analyzed; the antidepressant effect of ziprasidone is larger than that of placebo in these analyses. In the two active-comparator studies, improvement in depression and anxiety symptoms in patients receiving ziprasidone was comparable to the improvement in olanzapine recipients but greater than the improvement in risperidone recipients. A smaller study (Kinon et al. 2006a) compared the efficacy of olanzapine and ziprasidone over 24 weeks in the treatment of schizophrenia or schizoaffective disorder patients with prominent depressive symptoms. Both treatment groups had significant improvements in depressive symptoms for the first 8 weeks, with olanzapine-treated patients showing significantly greater improvements in depressive symptoms at study endpoint. However, the interpretation of this study is limited by that fact that a substantial number of patients (52.8% of $N = 394$ at study entry) received concurrent treatment with nonstandardized antidepressants. These overall results provide preliminary evidence suggesting that ziprasidone, like some other antipsychotic agents, may be effective in treating comorbid depressive symptoms in patients with schizophrenia and schizoaffective disorder.

Efficacy for social deficits and improvement in quality of life

To date, the NIMH CATIE study is the largest trial examining the effect of ziprasidone and other antipsychotics on psychosocial functioning in patients with schizophrenia (Swartz et al. 2007). This study used the Quality of Life Scale, a widely used clinician-rated measurement (Heinrichs et al. 1984), to assess changes in social functioning, interpersonal relationships, vocational functioning, and psychological well-being. One-third of the patients in the phase I study antipsychotic treatment groups made modest improvements on the Quality of Life Scale from baseline to the 12-month endpoint (average effect size, 0.19 standard deviation units), with no significant differences between the agents.

The effect of ziprasidone on social functioning has also been evaluated using the prosocial subscale of the PANSS, including items related to active and passive social avoidance, emotional withdrawal, stereotypical thinking, and suspiciousness (Purnine et al. 2000). In three separate but related studies from one group, stable patients taking either conventional antipsychotics, olanzapine, or risperidone were switched to ziprasidone and followed for 6 weeks with ratings of safety, efficacy, and effectiveness (Weiden et al. 2003b). Six weeks of treatment with ziprasidone in all three prior-treatment groups resulted in significant improvement on the PANSS prosocial subscale (Loebel et al. 2004). The

interpretation of results as being specific to ziprasidone use, rather than being simply an effect of extended, closely monitored treatment, is complicated by the absence of a control condition other than the prior-treatment baseline ratings.

Treatment-Resistant Schizophrenia

The efficacy of ziprasidone for treatment-resistant schizophrenia was evaluated in a 12-week double-blind chlorpromazine comparator study (*N* = 306 patients), with treatment-resistant status defined by failure to achieve criterion-level response after 6 weeks of prospective treatment with haloperidol (Kane et al. 2005). The mean daily dosage of ziprasidone at study endpoint was approximately 154 mg, compared with a mean daily chlorpromazine dosage of approximately 744 mg. Treatment with ziprasidone produced significantly greater improvement at endpoint in PANSS negative subscale scores compared with chlorpromazine. In addition, ziprasidone treatment was associated with a 1.3-fold higher likelihood of achieving a 50% reduction in BPRS total score compared with chlorpromazine treatment.

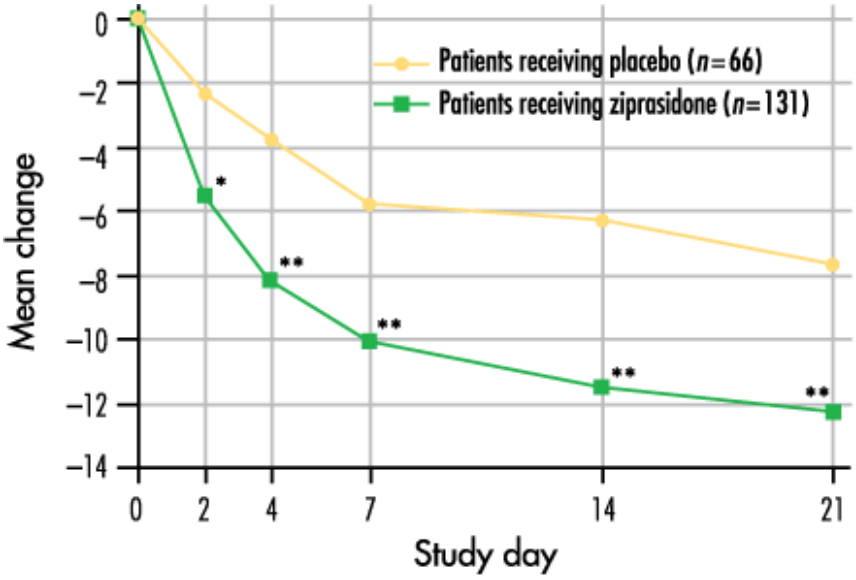
Switching From Other Antipsychotics

As discussed above, evidence suggests that the efficacy of ziprasidone is comparable to that of other atypical and conventional antipsychotics during both acute and maintenance treatment of schizophrenia and schizoaffective disorder. Subsequent sections provide evidence to support the safety, particularly the cardiometabolic safety, of ziprasidone compared with other antipsychotics (see "Side Effects and Toxicology" section). These results support interest in the clinical outcomes associated with switching from antipsychotic treatment with other agents to treatment with ziprasidone.

Three open-label, medication-switching studies evaluated the effect of switching to ziprasidone on measures of efficacy, safety, and tolerability, as well as the effect of different titration schedules on the outcome (Weiden et al. 2003b). In each study, patients were randomly assigned to one of three switching strategies to be completed in 1 week:

1. Immediate discontinuation of the previous antipsychotic and immediate starting of ziprasidone the next day
2. Lowering the dose of the previous antipsychotic by half while simultaneously starting ziprasidone
3. Overlapping the start of ziprasidone with the full dosage of the prior antipsychotic and then gradually reducing the prior antipsychotic dosage after 4 days of ziprasidone therapy.

For all switching strategies, the starting dosage of ziprasidone was 80 mg/day (40 mg twice daily), with subsequent dosage adjustments based on clinical judgment. In one study, patients taking high-potency conventional antipsychotics (*N* = 108) were switched to ziprasidone. In the second study, patients (*N* = 58) were switched from risperidone to ziprasidone. In the third study, patients (*N* = 104) were switched from olanzapine to ziprasidone. Discontinuation rates were low in all three studies, ranging from 2%–6% for lack of efficacy to 6%–9% for adverse events. In study completers, statistically significant improvements were observed on PANSS total, PANSS positive subscale, PANSS negative subscale, and BPRSd total scores. Different switching strategies were not associated with a different likelihood of trial completion or different magnitude of clinical response. The absence of active or placebo control subjects in this set of studies, in combination with the similarly favorable response profile, limits the interpretation of results with respect to changes in psychiatric symptoms associated with the change in medications.



Bipolar Disorder

Acute Mania

Ziprasidone has received regulatory approval (e.g., by the FDA) for the acute treatment of bipolar mania, with efficacy for acute mania demonstrated in two double-blind, placebo-controlled trials, each 3 weeks in duration, in patients with bipolar I disorder (P. E. Keck et al. 2003b; Potkin et al. 2005). In both studies, onset of action was rapid (within 48 hours) and sustained through 3 weeks of treatment in patients with bipolar mania or bipolar mixed states, with or without psychotic symptoms (results of P. E.

Keck et al. [2003b] are shown in Figure 33–5). At endpoint, approximately half of the treated patients from both studies met response criteria for mania (≥50% reduction in Mania Rating Scale [MRS] scores).

A growing number of placebo-controlled trials evaluating the efficacy of short-term monotherapy with various atypical antipsychotics, including ziprasidone, olanzapine, risperidone, quetiapine, and aripiprazole, have demonstrated comparable improvement in symptoms of mania (Bowden et al. 2005; Hirschfeld et al. 2004; P. E. Keck et al. 2003a, 2003b; Khanna et al. 2005; McIntyre et al. 2005; McQuade et al. 2003; Potkin et al. 2005; Sachs et al. 2006; Smulevich et al. 2005; Tohen et al. 1999, 2000); Weisler et al. 2003). Two recent large meta-analyses of randomized, placebo-controlled trials have examined the relative efficacy of various atypical antipsychotics for the adjunctive treatment of mania (Perlis et al. 2006; Scherk et al. 2007). Although the statistical results of the two meta-analyses are similar, the authors of each study interpreted the results somewhat differently. Perlis et al. (2006) concluded that add-on therapy with atypical antipsychotics (ziprasidone, olanzapine, quetiapine, and risperidone) conferred an additional benefit over monotherapy with a traditional mood stabilizer in reducing manic symptoms, with no difference in efficacy among the drugs. Scherk et al. (2007) also concluded that atypical antipsychotics as a group were significantly superior to placebo as adjunctive treatment for mania, but that ziprasidone and other individual agents may not be significantly superior to placebo in the adjunctive treatment of manic symptoms. Although regulatory approvals for the individual agents have supported the efficacy and safety of a number of individual antipsychotics for the acute treatment of mania, including ziprasidone (which is also approved for the acute treatment of mixed states), prospective, head-to-head comparator trials may be required to clarify whether differences suggested by some meta-analyses are clinically meaningful or are related to differences in study design or methodology.

Maintenance Treatment

Two 52-week open-label extension studies support the safety, tolerability, and sustained efficacy of

ziprasidone as maintenance treatment for bipolar disorder (P. E. Keck et al. 2004; Weisler et al. 2004). P. E. Keck et al. (2004) reported that treatment with ziprasidone (*n* = 127; mean daily dosage, 123 mg) was associated with significantly lower MRS and CGI-S scores compared with baseline, beginning as early as the first week. Overall, improvements in manic symptoms achieved during acute treatment continued to consolidate during maintenance treatment with ziprasidone. During 52 weeks of treatment, only 6% of patients discontinued ziprasidone use due to relapse of mania. Similarly, only 4% of patients discontinued due to a clinical switch into depression. An important caveat regarding these results is the high rate of attrition observed by the end of 1 year, which is consistent with long-term studies involving other atypical antipsychotics but which limits the full interpretation of results. Similar results were observed in a separate extension study of adjunctive ziprasidone therapy (mean daily dosage, 92.6 mg) by Weisler et al. (2004); this study reported a mean improvement from baseline in MRS scores at all points throughout the study (Patel and Keck 2006).

Treatment-Resistant Depression

Although there have been no randomized studies, small uncontrolled studies have prompted interest in the efficacy of ziprasidone for treatment-resistant depression (Barbee et al. 2004; Jarema 2007; Papakostas et al. 2004). Papakostas et al. (2004) reported the results of a small study of 20 patients with major depression resistant to treatment with selective serotonin reuptake inhibitors (SSRIs). Open-label treatment with ziprasidone for 6 weeks, adjunctive to ongoing SSRI treatment, was evaluated with an intent-to-treat analysis that identified 10 treatment responders (defined as having a ≥50% decrease in depressive symptoms as measured by the Ham-D-17). In a smaller retrospective chart review (Barbee et al. 2004), in which only 5 of 10 patients were exposed to ziprasidone for at least 6 weeks, 1 patient met criteria for being a treatment responder (requiring ratings of "very much improved"). Randomized studies are needed to evaluate the efficacy and safety of ziprasidone for patients with treatment-resistant depression.

Agitation

The efficacy of intramuscular ziprasidone for the treatment of agitated psychosis has been demonstrated in two randomized, double-blind trials (2 mg im vs. 20 mg or 10 mg im, respectively, with up to three more doses allowed as needed at 4-hour or 2-hour intervals, respectively), leading to regulatory approval by the FDA (Daniel et al. 2001; Lesem et al. 2001). Treatment with single 10- or 20-mg doses leads to rapid reductions in symptom severity, with most patients having remission of agitation within 1 hour of dosing. Treatment with intramuscular ziprasidone is associated with a relatively low rate of concomitant benzodiazepine use (<20%). Sequential use of intramuscular ziprasidone followed by oral ziprasidone for the treatment of acute psychotic agitation has demonstrated superior efficacy, compared with sequential use of intramuscular and oral haloperidol, in two 7-day randomized, open-label trials (Brook et al. 2000; Swift et al. 1998) as well as in a 6-week randomized, single-blind, flexible-dose study (Brook et al. 2005). Clinical improvement occurred more rapidly than with haloperidol in one study, and as quickly as 30 minutes after the first intramuscular administration of ziprasidone (Swift et al. 1998). Cumulative data from these studies indicate that intramuscular ziprasidone can rapidly control agitation and psychotic symptoms and provide greater mean improvements in acute agitation than seen with intramuscular haloperidol (e.g., greater mean improvements in BPRS total score, agitation, and CGI-S score) (Brook 2003).

One uncontrolled prospective study of 21 patients (Barak et al. 2006) and a retrospective chart review of 35 cases (Kohen et al. 2005) evaluated the safety and efficacy of intramuscular ziprasidone for treatment of acute psychotic agitation in the elderly; both suggested that ziprasidone is effective and well tolerated in the elderly. Larger controlled studies are necessary to confirm these results and the safety of ziprasidone in this patient population.

Pediatric Patients

Ziprasidone has not to date been approved by the FDA for use in children or adolescents, and published

data concerning the safety and efficacy of ziprasidone use in children and adolescents remain limited. To date, there has been one randomized, controlled trial of ziprasidone in children and adolescents (ages 10–17 years) with bipolar disorder (Versavel et al. 2005). In this study, treatment with ziprasidone was associated with improvement in mania and overall psychopathology. Two retrospective chart reviews of hospitalized children and adolescents reported that intramuscular ziprasidone demonstrated efficacy in the treatment of acute agitation and aggression (Staller 2004) and that intramuscular ziprasidone was as effective as intramuscular olanzapine in pediatric patients (Khan and Mican 2006). Two additional small studies suggested that ziprasidone may reduce tic severity in children and adolescents with Tourette's syndrome (Sallee et al. 2006) and may improve symptoms of aggression, agitation, and irritability in children and adolescents with autism (McDougle et al. 2002).

SIDE EFFECTS AND TOXICOLOGY

Ziprasidone has a favorable tolerability profile based on both short- and long-term clinical trials (Daniel 2003; Pfizer Inc. 2004). The four most common treatment-related adverse events associated with oral ziprasidone in short-term premarketing, placebo-controlled trials for schizophrenia were somnolence (14%), EPS (14%), nausea (10%), and constipation (9%) (Pfizer Inc. 2008). In subsequent clinical trials, treatment with ziprasidone was associated with a low occurrence of adverse events, most of which were considered mild to moderate in severity (Arango et al. 2007; Arato et al. 2002; Lieberman 2007; Nemeroff et al. 2005; Weiden et al. 2002, 2003b). In addition to the comprehensive listing of potential adverse events available in the full U.S. prescribing information (USPI) (Pfizer Inc. 2008), published case reports offer accounts of various rare adverse events that may be associated with the use of ziprasidone (Akkaya et al. 2006; Kaufman et al. 2006; Miodownik et al. 2005; Murty et al. 2002; Villanueva et al. 2006). Intramuscular ziprasidone shows a favorable tolerability profile similar to that of oral ziprasidone. In premarketing trials, the most common side effects of intramuscular ziprasidone (those with an incidence of >5% and an incidence greater than that seen in placebo recipients) were somnolence (20%), headache (13%), and nausea (12%) (Pfizer Inc. 2008). Pooled data from more recent clinical trials of intramuscular ziprasidone indicate that most treatment-related adverse events were mild to moderate in severity, with the most common side effects being headache, nausea, dizziness, insomnia, anxiety, and pain at the injection site (Daniel 2003; Zimbroff et al. 2002). Ziprasidone is considered a Category C drug in pregnancy. Although some specific developmental effects have been noted in animal studies at dosages ranging from 0.5 to 8.0 times the maximal recommended human dosage (Pfizer Inc. 2008), there are as yet no similar reports of such effects in humans. The reader is advised to consult the current USPI for a detailed listing of potential adverse drug effects identified in the regulatory approval process and postmarketing surveillance.

The FDA recently required the addition of black box warnings in the USPI regarding an increased risk of mortality associated with the use of both atypical and conventional antipsychotics used in elderly patients with dementia-related psychosis. Observed causes of death have been varied, and the mechanism of any drug effect in schizophrenia remains uncertain (Pfizer Inc. 2008). In particular, it remains unclear to what extent these uncontrolled observations of increased mortality are due to specific drug effects or to the advanced medical risk characteristics of patients with dementia or delirium who tend to receive these medications (Farber et al. 2000; Rochon et al. 2008). Regulatory interest in drug effects on cerebrovascular risk (i.e., risk of stroke) in the elderly, in contrast to generalized considerations of cardiovascular risk factors (e.g., myocardial infarction and stroke) discussed below (see "Metabolic Adverse Events" and "Cardiac Conduction, Including Ventricular Depolarization and Repolarization"), has also been focused on some atypical antipsychotics. Studies including those by Street et al. (2000), Wooltorton (2002), and De Deyn et al. (2004) have suggested that olanzapine and risperidone treatment may be associated with an increase in the risk of cerebrovascular adverse events and mortality. Again, possible mechanisms underlying hypothesized effects remain unclear, with some evidence suggesting that patient characteristics other than the specific antipsychotic used may be more significant predictors of cerebrovascular event risk than any drug-specific effects (Finkel et al. 2005).

Clinical experience with ziprasidone in the years following initial U.S. approval has suggested that a small

subgroup of patients may experience insomnia or what has been characterized as *activation* or *akathisia* soon after initiation of treatment (Nemeroff et al. 2005). These presentations have been described as transient manifestations of anxiety, restlessness, insomnia, increased energy, or hypomania-like symptoms, occurring most commonly at what is now considered the lower end of the dosage range. Anecdotal reports suggest that starting dosages of 120 mg/day or greater and more rapid dose titration can substantially reduce the incidence of these clinical presentations (Weiden et al. 2002). These anecdotal clinical observations are consistent with controlled experimental evidence indicating that a significantly lower rate of discontinuation occurs in patients who begin ziprasidone therapy at higher dosages (120–160 mg/day) than in patients who receive initial dosages of 80 mg/day or less (Joyce et al. 2006). Several mechanisms may explain these observations:

- First, ziprasidone, like some of the other newer antipsychotics and many under development, is less intrinsically sedating than many other antipsychotics in current widespread use (e.g., due to less H_1 receptor antagonism), so that patients initiating ziprasidone treatment after months or years of receiving a different, more sedating therapy may experience initial difficulties adjusting to the new level of dosing time–specific (e.g., at bedtime) or around-the-clock sedation.
- Second, as discussed above (see "Pharmacological Profile" and "Indications and Efficacy" sections earlier in chapter) many patients have been treated with ziprasidone at doses that were insufficient to achieve optimal D_2 receptor blocking, leading to undertreatment of the underlying illness compared with what might have been achieved with an appropriately dosed prior therapy.
- Furthermore, ziprasidone underdosing with respect to D_2 receptor binding can produce a well-understood but unwanted pharmacodynamic situation with respect to the differential balance of 5-HT_{2C} receptor antagonism relative to D_2 receptor antagonism. As illustrated in Figure 33–3, using ziprasidone doses at the lower end of the clinical dosage range can allow 5-HT_2 receptors to reach 50% of maximal receptor occupancy or more, well before clinically significant levels of D_2 occupancy are achieved (Mamo et al. 2004). 5-HT_{2C} antagonist activity at this level disinhibits cortical monoaminergic neurotransmission (e.g., dopamine release), which, in the absence of sufficient D_2 blockade, may lead to clinically relevant excess monoaminergic neurotransmission (Bonaccorso et al. 2002; Pozzi et al. 2002).

Clinicians commonly address these potential issues through appropriate dosing and through the transient, targeted use of concomitant medication strategies (e.g., adjunctive benzodiazepine treatment) for relevant patients starting new treatment in the acute inpatient setting or for stable outpatients needing a smooth transition to new therapy.

Two other areas of potential adverse drug effects deserve further discussion: drug effects on risk for EPS and drug effects on cardiometabolic risk factors (e.g., changes in weight, plasma lipids, and glucose). These adverse-event domains are notable as areas of considerable clinical and research interest. For example, drug effects on EPS and cardiometabolic risk factors such as weight and plasma lipid level changes were the only side effect categories observed to contribute to differential rates of treatment discontinuation in the primary analysis of the NIMH-funded phase I CATIE study (Lieberman et al. 2005).

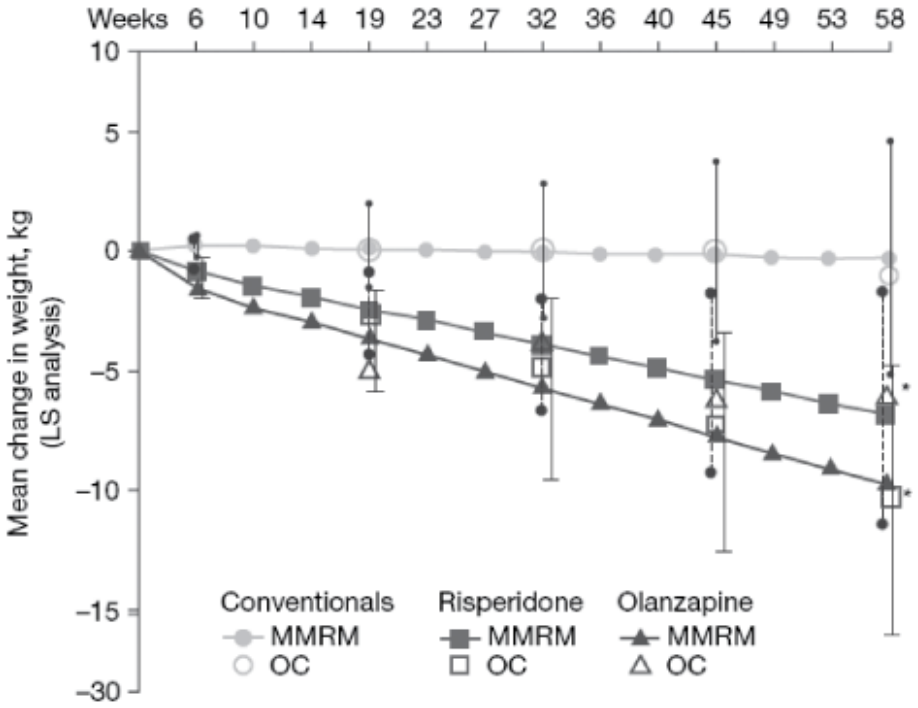
Extrapyramidal Side Effects

Short-term trials indicate that treatment with ziprasidone is associated a measurably larger incidence of EPS than treatment with placebo (Pfizer Inc. 2008; Potkin et al. 2005). In contrast, data from a 52-week trial (Arato et al. 2002) indicate that the incidence of abnormal movement disorders during treatment with ziprasidone is comparable to the incidence during placebo treatment. Other long-term studies suggest a low (<6%) incidence of treatment-related EPS (Arango et al. 2007; Kudla et al. 2007). Both active-comparator studies and medication-switching studies suggest that ziprasidone is associated with fewer EPS than risperidone (Addington et al. 2003; Weiden et al. 2003a, 2003b) or conventional antipsychotics (Hirsch et al. 2002; Weiden et al. 2003a, 2003b). Comparing ziprasidone and olanzapine, a drug with intrinsic antimuscarinic activity as well as 5-HT_2 receptor antagonist activity, one direct comparison study indicates that treatment with olanzapine is associated with fewer EPS (Kinon et al. 2006a), whereas two other direct comparison studies (Breier et al. 2005; Simpson et al. 2002) and one

medication-switching study (Weiden et al. 2003b) have reported that both drugs exhibit a similar liability for EPS. With respect to akathisia, one comparison study indicates that less akathisia occurs with olanzapine use (Breier et al. 2005), whereas another study suggests no difference in akathisia rates with olanzapine versus ziprasidone (Kinon et al. 2006a). Results from phase I and phase II of the large-scale CATIE trial suggest no significant differences between ziprasidone, perphenazine, olanzapine, quetiapine, and risperidone in the incidence of EPS and akathisia (Lieberman 2007; Lieberman et al. 2005; Stroup et al. 2006). However, the perphenazine arm in the CATIE study was restricted to patients who did not already have tardive dyskinesia, suggesting a possible selection bias toward patients less likely to experience EPS. Despite this advantage, the perphenazine group still had the highest rate of dropouts due to EPS, suggesting along with other lines of evidence that clinically meaningful EPS are more common in patients treated with conventional agents like perphenazine.

Intramuscular ziprasidone has been tolerated at dosages of up to 80 mg/day with a low liability for EPS (Daniel 2003; Daniel et al. 2001; Lesem et al. 2001). Both intramuscular ziprasidone use and sequential intramuscular/oral ziprasidone use are associated with a lower incidence of treatment-related movement disorders than intramuscular haloperidol use (Swift et al. 1998; Zimbroff et al. 2002) and sequential intramuscular/oral haloperidol use (Brook et al. 2000, 2005). Although the results of controlled experimental studies indicate a generally low risk of EPS with ziprasidone, there have been several uncontrolled observational reports of EPS-related adverse events co-occurring with ziprasidone treatment and, in many cases, concomitant treatment with other agents (Dew and Hughes 2004; Duggal 2007; M. E. Keck et al. 2004; Mason et al. 2005; Papapetropoulos et al. 2005; Ramos et al. 2003; Rosenfield et al. 2007; Weinstein et al. 2006; Yumru et al. 2006; Ziegenbein et al. 2003).

Metabolic Adverse Events



Adverse medication effects on modifiable risk factors for cardiovascular disease and type 2 diabetes mellitus have become an important topic of clinical, research, and regulatory concern, based in part on the increased prevalence of these disease states and associated premature mortality observed in patients with major mental disorders like schizophrenia and bipolar disorder (Brown 1997; Brown et al. 2000; Colton and Manderscheid 2006; Harris and Barraclough 1998; Hennekens et al. 2005; Joukamaa et al. 2001; Osby et al. 2000, 2001). Modifiable cardiometabolic risk factors include obesity, hyperglycemia, dyslipidemia, hypertension, and smoking, all prevalent conditions in patients with major mental disorders, with substantial evidence that primary and secondary prevention approaches are underutilized in these patients (Allison et al. 1999a; Brown et al. 2000; Druss and Rosenheck 1998; Druss et al. 2000, 2001; Frayne et al. 2005; Hippisley-Cox et al. 2007; McEvoy et al. 2005; Nasrallah et al. 2006; Newcomer and Hennekens 2007). In particular, use of recommended monitoring of changes in weight and in plasma glucose and lipid levels during antipsychotic treatment has heightened interest in cardiometabolic risk effects that may go undetected during the course of treatment (American Diabetes Association 2004; Morrato et al. 2008). All currently available antipsychotic medications are associated with a risk of weight gain, as well as potential adverse effects on plasma glucose and lipid levels, although there is substantial variability in the magnitude of these effects across individual agents (Casey et al. 2004; Eli Lilly 2008; "Eli Lilly updates label warning for Zyprexa" 2007; Newcomer 2005). Potential adverse treatment effects on body weight can be predicted to increase the risk for cardiovascular disease as well as for conditions like type 2 diabetes, commonly involving corresponding, measurable increases in insulin resistance, dyslipidemia, and hyperglycemia (Fontaine et al. 2001; Haupt et al. 2007; Koro et al. 2002a, 2002b).

Treatment with ziprasidone is associated with a relatively small risk of clinically significant increases in body weight. An analysis of available studies with this agent and other antipsychotics, both first- and second-generation antipsychotics (Allison et al. 1999b), estimated a 0.04-kg weight gain over a 10-week treatment period with ziprasidone, identifying ziprasidone as having one of the lowest estimated effects on body weight of those analyzed. In a 6-week randomized, controlled trial in patients with acute exacerbations of schizophrenia or schizoaffective disorder, treatment with ziprasidone 80 mg/day produced a median increase in body weight of 1 kg, compared with no change in median weight with ziprasidone 160 mg/day or placebo (Daniel et al. 1999). In a 28-week study of outpatients with

schizophrenia, mean changes in body weight from baseline to endpoint were similar during treatment with ziprasidone (+0.31 kg) and haloperidol (+0.22 kg) (Hirsch et al. 2002). In a 28-week study comparing the effects of ziprasidone and olanzapine, ziprasidone-treated patients experienced a small decrease in mean body weight (–1.12 kg) compared with a statistically and clinically different 3.06-kg mean increase in body weight observed with olanzapine treatment (Hardy et al. 2003; Kinon et al. 2006a). Reductions in body weight were also associated with ziprasidone treatment in the 1-year Ziprasidone Extended Use in Schizophrenia study of patients with chronic, stable schizophrenia (Arato et al. 2002); this study reported mean decreases from baseline of 2.7 kg, 3.2 kg, and 2.9 kg reported with 40 mg/day, 80 mg/day, and 160 mg/day dosages of ziprasidone, respectively, compared with a 3.6-kg decrease observed with placebo treatment. Results from the phase I and phase IIT CATIE studies provide further confirmation that treatment with ziprasidone has a low intrinsic risk for producing clinically significant weight gain, with 6%–7% of ziprasidone recipients demonstrating a 7% or greater increase from baseline body weight compared with, for example, 27%–30% of olanzapine recipients (Lieberman 2007; Stroup et al. 2006). In the phase I CATIE study, ziprasidone treatment was associated with a mean reduction in body weight of 0.14 kg (0.3 lb) per month of treatment, compared with a mean increase of 0.91, 0.23, and 0.18 kg/month (2.0, 0.5, and 0.4 lb/month) during treatment with olanzapine, quetiapine, and risperidone, respectfully, the other atypical antipsychotics tested (Lieberman et al. 2005).

It is important to note that the ranking of weight gain liability for individual medications appears to apply in patients being treated for their first psychotic episode or during early drug exposure but perhaps not during chronic treatment, although there have been fewer studies in this area and initial courses of treatment can clearly be associated with greater weight gain than subsequent courses of treatment (McEvoy et al. 2007). In addition, chronically treated patients switching treatment from a medication with greater weight gain liability to a medication with less weight gain liability are likely to lose body weight in relation to that medication change, an effect that likely underlies the mean reductions in weight noted in some of the trials with ziprasidone discussed above. The magnitude of change in body weight during treatment with ziprasidone varies as a function of the weight gain liability of the prior treatment: the greatest potential for weight loss is associated with switching from previous treatments with the greatest weight gain liability (Weiden et al. 2008). For example, 6 weeks of ziprasidone therapy was associated with statistically significant decreases in mean body weight from baseline in patients switched from olanzapine (–1.8 kg) and from risperidone (–0.9 kg), whereas patients switched from high-potency conventional antipsychotics such as haloperidol experienced a small increase in weight (+0.3 kg) (Weiden et al. 2008). The 1-year extension of this medication-switching study indicated that weight loss was progressive and persistent throughout the 1-year period for patients who switched from olanzapine (–9.8 kg, or 10.3% of baseline body weight) and from risperidone (–6.9 kg, or 7.8% of baseline) (Figure 33–6; Weiden et al. 2008). Another study found similar significant decreases in weight in patients treated for 6 months with ziprasidone who were switched from olanzapine (–7.0 kg) and from risperidone (–2.2 kg) (Montes et al. 2006).

Ziprasidone's effects on plasma glucose and lipid levels are best understood as a function of treatment-related changes in adiposity. Whereas some antipsychotics, such as clozapine and olanzapine, have been reported to produce adiposity-independent effects on insulin sensitivity, and related changes in glucose and lipid metabolism, ziprasidone has demonstrated no similar adiposity-independent effects in this same experimental paradigm (Houseknecht et al. 2007). In general, increases in adiposity are associated with decreases in insulin sensitivity in individuals taking or not taking antipsychotic medications, with reduced insulin sensitivity leading to increased risk for hyperglycemia, dyslipidemia, and other adverse changes in cardiometabolic risk indicators (Haupt et al. 2007; Newcomer and Haupt 2006).

Ziprasidone's relatively low risk for drug-related increases in weight is therefore not surprisingly associated with a low risk for adverse effects on plasma lipids and other metabolic indices. Both short- and long-term studies have shown little significant adverse effect of ziprasidone on glucose levels, plasma insulin levels, insulin resistance, or fasting and nonfasting lipid levels (Daniel et al. 1999; Glick et al. 2001; Rettenbacher et al. 2006; Simpson et al. 2004a, 2005) in contrast to the degree of adverse effects detected with some active comparators. For example, olanzapine treatment can produce statistically significant increases in fasting glucose and insulin levels (Glick et al. 2001; Hardy et al. 2003; Simpson et al. 2002, 2005) as well as fasting lipids and insulin resistance calculated by homeostasis model assessment (Simpson et al. 2004a, 2005). In the CATIE Phase I study, olanzapine-treated patients demonstrated drug exposure–adjusted mean increases in blood glucose (+13.7 ± 2.5 mg/dL) and glycosylated hemoglobin (hemoglobin A_{1c} [HbA_{1c}]) (+0.4 ± 0.07%), plasma triglycerides (+40.5 ± 8.9

mg/dL), and total cholesterol (+9.4 ± 2.4 mg/dL), whereas ziprasidone treatment was associated with minimal drug exposure–adjusted mean increases in blood glucose (+2.9 ± 3.4 mg/dL) and HbA_{1c} (+0.11 ± 0.09%), and decreases in plasma triglycerides (–16.5 ± 12.2 mg/dL) and total cholesterol (–8.2 ± 3.2 mg/dL) (Lieberman 2007). In the CATIE Phase IIT study, olanzapine-treated patients again had the greatest drug exposure–adjusted mean increases in HbA_{1c} (+0.97 ± 0.3%), triglycerides (+94.1 ± 21.8 mg/dL), and total cholesterol (+17.5 ± 5.2 mg/dL), with quetiapine treatment associated with drug exposure–adjusted mean increases in blood glucose (+1.2 ± 6.0 mg/dL) and HbA_{1c} (+0.61 ± 0.3%), glucose (+13.8 ± 5.9 mg/dL), triglycerides (+39.3 ± 22.1 mg/dL), and total cholesterol (+6.5 ± 5.3 mg/dL). In contrast, ziprasidone-treated patients in CATIE Phase IIT showed minimal drug exposure–adjusted mean increases in blood glucose (+0.8 ± 5.6 mg/dL) and HbA_{1c} (+0.46 ± 0.3%) and decreases in triglycerides (–3.5 ± 20.9 mg/dL) and total cholesterol (–10.7 ± 5.1 mg/dL) (Stroup et al. 2006).

Similar to the effect of prior treatment conditions on changes in weight during treatment with ziprasidone, improvements in plasma lipid levels observed in the CATIE study can best be understood as the effect of switching from a previous treatment that is associated with larger adverse effects on lipid metabolism to a treatment with minimal adverse effects. Weiden et al. (2003a) noted that ziprasidone treatment was associated with significant decreases from baseline in both median nonfasting triglyceride levels and median nonfasting total cholesterol levels at the end of the 6-week treatment period in patients whose prior medication was olanzapine or risperidone, with minimal change following prior treatment with high-potency conventional agents like haloperidol. Notably, the reductions in lipids observed in this study occurred within the first 6 weeks of initiating treatment with ziprasidone, with substantial reductions in total cholesterol (>20 mg/dL) and plasma triglycerides (78 mg/dL) in the patients previously treated with olanzapine. In the 12-month extension of this study, the reductions achieved in the initial weeks following the switch from prior treatment were sustained during continued treatment with ziprasidone (Weiden et al. 2008).

Cardiac Conduction, Including Ventricular Depolarization and Repolarization

Some medications, including psychotropics, can increase the duration of the QTc interval (the QT interval corrected for heart rate). Basic research suggests plausible mechanisms by which an increase in the QTc interval could increase the risk of sudden cardiac death, and clinical investigations suggest that certain small subgroups of the general population may have an increased risk of sudden cardiac death, for example, those with a family history of congenital long-QT syndrome (>500 msec) and those who concomitantly use drugs that markedly increase the QTc interval (e.g., by >60 msec) via either pharmacokinetic or pharmacodynamic interactions (Montanez et al. 2004). This has understandably led to regulatory interest in drug effects on the QTc interval. It should be noted that epidemiological studies in the general population suggest that modest prolongations of the QTc interval are not a risk factor for cardiovascular mortality or sudden death, so any risk in the general population of modest QTc prolongations is likely to be small and difficult to detect reliably (Montanez et al. 2004). Compared with risks like obesity, hypercholesterolemia, diabetes, hypertension, physical inactivity, or cigarette smoking, each with well-characterized effects in the general population, modest QTc prolongations are not a comparable risk factor for cardiovascular mortality or sudden death in the general population.

Against this background, thioridazine was recently required to add to its prescribing information a black box warning related to its QTc interval–prolonging effects, following decades of use. Other conventional antipsychotics, including haloperidol, are also associated with some risk of QTc prolongation (Gury et al. 2000; O'Brien et al. 1999). Investigators (Glassman and Bigger 2001) have estimated the rate of occurrence of torsades de pointes with conventional antipsychotics as "10–15 such events in 10,000 person-years of observation" (p. 1774). Ziprasidone, like some other antipsychotic agents, can induce orthostatic hypotension, particularly early in treatment exposure, which can lead to transient tachycardia, dizziness, or syncope (Swainston Harrison and Scott 2006). However, tachycardia has been observed to be infrequent and as common in patients treated with ziprasidone as in those treated with placebo (Swainston Harrison and Scott 2006). Tachycardia and syncope related to hypotension are to be distinguished from ventricular arrhythmias that can rarely occur in relation to QTc prolongation.

Ziprasidone treatment has been demonstrated to result in a modestly increased risk of QTc prolongation (Pfizer Inc. 2008). This QTc prolongation at C_{max} (mean increase, >15 msec) is 9–14 msec greater than that seen with risperidone, olanzapine, quetiapine, or haloperidol but approximately 14 msec less than that seen with thioridazine. Unlike the case with thioridazine, the modest effect of ziprasidone on the QTc interval is not worsened by the presence of commonly encountered inhibitors of drug metabolism. In clinical trials of ziprasidone monotherapy that report QTc changes as well as in case reports of ziprasidone overdosing (with doses up to 12,800 mg), there has been no evidence of any significant clinical sequelae such as torsades de pointes or sudden death (Arato et al. 2002; Arbuck 2005; Daniel 2003; Gomez-Criado et al. 2005; Harrigan et al. 2004; Insa Gómez and Gutiérrez Casares 2005; Levy et al. 2004; Lieberman 2007; Miceli et al. 2004; Montanez et al. 2004; Nemeroff et al. 2005; Taylor 2003; Weiden et al. 2002, 2003a). This is consistent with analyses of large population samples, which have failed to demonstrate any association between QTc duration and either cardiovascular or all-cause mortality (Goldberg et al. 1991). Rare cases of torsades de pointes have been reported in patients being treated with multiple medications including ziprasidone, but the incidence of these events appears to be below the known prevalence of torsades de pointes in community-based population samples (Heinrich et al. 2006). The USPI suggests that clinicians should nonetheless be cognizant of this potential risk and be aware of circumstances that may increase risk for the occurrence of torsades de pointes and/or sudden death in association with the use of any drugs that can prolong the QTc interval. Such circumstances include bradycardia, hypokalemia, or hypomagnesemia; concomitant use of other medications known to cause clinically significant QT prolongation (although an additive effect with ziprasidone has not been established); and presence of congenital long-QT syndrome. The USPI further states that ziprasidone should not be used in patients with significant cardiovascular conditions, such as uncompensated heart failure or a cardiac arrhythmia, or in those who have had a recent acute myocardial infarction or persistent QTc measurements of greater than 500 msec, and the prudent clinician might consider employing the same caution with many other antipsychotic and psychotropic medications currently in use.

CONCLUSION

Ziprasidone is the fourth atypical antipsychotic following clozapine to become available in the United States. This agent has a unique pharmacological profile with the highest 5-HT_{2A}/D_2 affinity ratio of currently available agents, potent serotonin and norepinephrine reuptake inhibition activity, agonist activity at 5-HT_{1A} receptors, and clinically relevant antagonist activity at various 5-HT_2 receptor subtypes. Ziprasidone has demonstrated rapid-onset and sustained efficacy for the treatment of schizophrenia, schizoaffective disorder, and bipolar mania, with promising evidence of favorable mood, cognitive, and prosocial effects. It is now available in an intramuscular formulation for the treatment of acute agitated psychoses.

Ziprasidone has a highly favorable safety and tolerability profile with limited potential for drug–drug and drug–disease interactions, critical issues for a patient population that generally has a high burden of medical comorbidity and is commonly exposed to complex polypharmacy. The adverse-effect profile of ziprasidone is particularly noteworthy in areas that are key to safety and tolerability in patients with major mental disorders such as schizophrenia and bipolar disorder, including low drug-related risk for EPS and minimal effects on cardiometabolic risk factors like obesity and dyslipidemia. As a fuller understanding of the cumulative risks associated with prolonged antipsychotic treatment develops, along with the risks and benefits of various commonly used adjunctive medications, it is likely that clinicians will increasingly appreciate individual medications with a wide spectrum of therapeutic activity and a favorable safety profile that support long-term use and optimize both medical and psychiatric outcomes.

Chapter 34. Drugs to Treat Extrapyramidal Side Effects

EXTRAPYRAMIDAL SIDE EFFECTS

History

The discovery of the therapeutic properties of chlorpromazine (Delay and Deniker 1952; Laborit et al. 1952) was soon followed by the description of its tendency to produce extrapyramidal side effects (EPS) that were indistinguishable from classical Parkinson's syndrome. A debate soon arose regarding the relationship between EPS and therapeutic efficacy. Flügel (1953) suggested that a therapeutic response from chlorpromazine required the development of EPS. Haase (1954) postulated that the neuroleptic dose that produced minimal subclinical rigidity and hypokinesis (i.e., the "neuroleptic threshold") was the minimal neuroleptic dose necessary for therapeutic antipsychotic effect and that it was manifested by micrographic handwriting changes. Other investigators also reported that EPS were necessary for therapeutic efficacy (see Denham and Carrick 1960; Karn and Kasper 1959).

Brooks (1956), on the other hand, suggested that "signs of parkinsonism heralded the particular effect being sought" (p. 1122) but that "the therapeutic effects were not dependent on extrapyramidal dysfunction. On the contrary, alleviation of such dysfunction, as soon as it occurred, sped the progress of recovery" (p. 1122). The need to develop EPS for therapeutic efficacy was also questioned by others. The differences in opinion regarding EPS and neuroleptic efficacy were partially attributable to differences in the definitions of EPS and in the methodologies of the studies (Chien and DiMascio 1967).

Haase's concept—that mild subclinical EPS manifested by handwriting changes were indicative of a therapeutic dose—was demonstrated in studies that found no difference in therapeutic response at doses beyond the neuroleptic threshold (Angus and Simpson 1970a; G. M. Simpson et al. 1970). Patients treated with doses beyond the neuroleptic threshold received significantly larger doses of medication without further therapeutic benefit. This finding has been discussed more fully (Baldessarini et al. 1988) and has been replicated (McEvoy et al. 1991).

When clozapine was first developed in 1960, it sparked little interest as a potential antipsychotic. Many investigators believed that EPS were necessary for antipsychotic effect, and clozapine appeared not to produce EPS. Even after studies showed that clozapine possessed antipsychotic activity, interest regarding commercial development was still limited. The hesitancy on the part of the pharmaceutical company was related to the belief held by many members of the psychiatric community—that is, that a drug could not have antipsychotic effect without producing EPS (Hippius 1989).

In contrast, the current goal in the development of new antipsychotic medications is to replicate the EPS profile of clozapine and to develop antipsychotics that do not produce EPS. This situation essentially brings the story of EPS full circle.

The terms used to name and characterize antipsychotic medications have also evolved. The term *tranquilizer* was initially introduced to characterize the psychic effects of reserpine. The term *neuroleptic,* derived from Greek and meaning "to clasp the neuron," was introduced to describe

chlorpromazine and the extrapyramidal effects that it produced (Delay et al. 1952). Until clozapine was approved for use, all commercially available drugs with antipsychotic properties possessed the following neuroleptic properties: blocking apomorphine and amphetamine-induced stereotypy; antagonizing the conditioned avoidance response; and producing catalepsy, elevated serum prolactin levels, and EPS. For that reason, all antipsychotic drugs were referred to as *neuroleptics.* With the subsequent development of clozapine and other antipsychotic drugs that possess reduced EPS profiles, the term *neuroleptic* no longer correctly categorizes all drugs with antipsychotic effects; therefore, the term *antipsychotic* is more accurate and more preferable.

Severe EPS can have a significantly negative effect on treatment outcome by contributing to poor compliance and exacerbation of psychiatric symptoms (Van Putten et al. 1981). Akathisia, in particular, is associated with poor clinical outcome (Levinson et al. 1990; Van Putten et al. 1984), increased violence (Keckich 1978), and even suicide (Shear et al. 1983). The presence of EPS early in treatment may place a patient at increased risk of developing tardive dyskinesia (TD) (Saltz et al. 1991). Orofacial TD may have a negative effect on the social acceptability of patients, even though they are often unaware of the movements (Boumans et al. 1994). Laryngeal dystonia can adversely affect speech, breathing, and swallowing (Feve et al. 1995; Khan et al. 1994) and can be potentially life-threatening (Koek and Pi 1989). Clearly, EPS are significant, need to be assessed, and should be minimized so that the overall treatment and health of patients may be optimized.

Types

Four types of EPS have been delineated, and the treatment of each type should be individualized. Acute dystonic reactions (ADRs) are generally the first EPS to appear and are often the most dramatic (Angus and Simpson 1970b). *Dystonias* are involuntary sustained or spasmodic muscle contractions that cause abnormal twisting or rhythmical movements and/or postures. ADRs tend to occur suddenly and generally involve muscles of the head and neck (as in torticollis, facial grimacing, or oculogyric crisis). Nearly 90% of all ADRs occur within 4 days of antipsychotic initiation or dosage increase, and virtually 100% of all ADRs occur by day 10 (Singh et al. 1990; Sramek et al. 1986). Although tardive dystonia can occur after this period, movements occurring beyond this time frame are much less likely to be ADRs. Instead, other conditions, including seizures, need to be considered.

Akathisia is the second type of EPS to appear. Akathisia, meaning "inability to sit," consists of both an objective restless movement and a subjective feeling of restlessness that the patient experiences as the need to move. It may be difficult for a patient to explain the sensation of akathisia, and the diagnosis can be missed. At times, patients may display the classical movements of akathisia, but they may not have the subjective distress—a condition that has been termed *pseudoakathisia,* which may be a type of tardive syndrome (Barnes 1990).

The third type of EPS, (pseudo)parkinsonism, is virtually indistinguishable from classical Parkinson's syndrome. The symptoms include a generalized slowing of movement (akinesia), masked facies, rigidity (including cogwheeling rigidity), resting tremor, and hypersalivation. Parkinsonism generally occurs after a few weeks or more of neuroleptic treatment. Akinesia needs to be differentiated from primary depression and the blunted affect of schizophrenia (Rifkin et al. 1975).

Tardive syndromes make up the fourth group of EPS. TD, although clearly associated with the use of antipsychotic medications, was actually described prior to the advent of antipsychotics (G. M. Simpson 2000). TD consists of irregular stereotypical movements of the mouth, face, and tongue and choreoathetoid movements of the fingers, arms, legs, and trunk. It tends to occur after months to years of use of antipsychotic medications. Patients frequently have no awareness of the abnormal movements. The lack of awareness may be related to frontal lobe dysfunction (Sandyk et al. 1993).

Tardive dystonia, a variant of TD, also generally emerges months to years after treatment with antipsychotics (Burke et al. 1982) Unlike in ADRs, the movements associated with tardive dystonia

tend to be persistent and more resistant to medical treatment (Kang et al. 1988).

Incidence

Ayd (1961) was the first to report the incidence of EPS, noting an overall incidence of 39%, with 21% demonstrating akathisia, 15% demonstrating parkinsonism, and only 2% having ADRs. Varying rates of occurrence, including much higher incidences of ADRs, have been reported since that time. A prospective study found that the range of incidence of ADRs was between 17% and 38%, with the higher rate occurring with haloperidol (Sramek et al. 1986). In general, higher prevalence rates for all types of EPS occur at higher doses and with higher-potency antipsychotics. In a series of surveys of 721 patients with schizophrenia conducted over 10 years, McCreadie (1992) found that the point prevalence was 27% for parkinsonism, 23% for akathisia or pseudoakathisia, and 29% for TD. Forty-four percent of patients had no movement disorder. A 10-year prospective study found that the overall incidence of TD within a group remained fairly stable—30% at baseline, 37% at 5 years, and 32% at 10 years (Gardos et al. 1994).

Data from the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) studies found the presence of probable TD by Schooler-Kane criteria in 212 (15%) of 1,460 subjects (D. D. Miller et al. 2005). Tardive dystonia has been reported to occur in 1%–2% of patients taking antipsychotic medications (Yassa et al. 1986).

Extrapyramidal movements have been reported to occur in 17%–29% of neuroleptic-naive patients with schizophrenia (Caligiuri et al. 1993; Chatterjee et al. 1995). This finding raises questions regarding the role of antipsychotics in the etiology of TD (see G. M. Simpson et al. 1981).

These data refer to first-generation typical antipsychotics. Data from the CATIE trials include subjects treated with second-generation atypical antipsychotics as well as typical antipsychotics. The presence of probable TD by Schooler-Kane criteria was found in 212 of 1,460 subjects (15%), which is lower than rates noted above (D. D. Miller et al. 2005). The incidence for all types of EPS has been shown to be less with the second-generation atypical antipsychotics.

Etiology

The exact mechanisms involved in the production of EPS are not known. Control of motor activity apparently involves an interaction between nigrostriatal dopaminergic, intrastriatal cholinergic, and γ-aminobutyric acid (GABA)–ergic neurons (Côté and Crutcher 1991). Extrapyramidal movements of parkinsonism and dystonia classically have been thought to result from antipsychotic blockade of dopaminergic nigrostriatal tracts, resulting in a relative increase in cholinergic activity (Snyder et al. 1974). Drugs that either decrease cholinergic activity or increase dopaminergic activity reduce EPS, presumably by restoring the two systems to their previous equilibrium, as demonstrated in ADRs in monkeys (Casey et al. 1980). This feature is the basis for the use of anticholinergics in the treatment of EPS.

The etiology of TD is thought to result from more complex changes, which include increased dopamine receptor sensitivity following prolonged dopamine blockade (Gerlach 1977). The production of EPS probably involves more complex interactions of other factors and receptor types, which have become the subject of investigation.

Decreased serum calcium has been associated with increased EPS. Calcium is involved in the function of the cholinergic system and in the metabolism of dopamine (Kuny and Binswanger 1989), and antipsychotic drugs bind to the calcium-dependent activator of several enzyme systems. (Calmodulin has been studied by el-Defrawi and Craig [1984].)

GABA may have an effect on EPS through inhibitory feedback on the dopaminergic system. Reduced GABA synthesis and reduced GABA levels have been found with TD (Gunne et al. 1984; Thaker et al.

1987). The effect of GABA on ADRs is not as clear. ADRs in baboons were found to be increased by drugs that increased GABA levels, as well as by drugs that decreased GABA (Casey et al. 1980).

β-Adrenergic mechanisms may be involved in TD, akathisia, and tremor (Wilbur et al. 1988). Clozapine is a potent α_1-adrenergic receptor antagonist in the brain, causing α_1 receptor upregulation and increased noradrenergic metabolism, factors that may affect the EPS profile of clozapine (Baldessarini et al. 1992).

Free radicals, possibly produced by chronic neuroleptic use, have been proposed as contributors to the development of neuropathic damage and TD. Vitamin E, as an antioxidant that binds free radicals, has been suggested as a treatment for TD by limiting the process (Cadet et al. 1986). Levels of lipid peroxides, theoretically produced by free radicals, have not been found to correlate with TD (McCreadie et al. 1995), nor have changes in levels correlated with treatment with vitamin E, although it was noted that these changes could be occurring centrally (Corrigan et al. 1993).

A somewhat related theory suggests that increased iron levels in the basal ganglia may contribute to TD because of the involvement of iron in the production of free radicals (Ben-Shachar and Youdim 1987). However, neuroimaging and pathological studies have not demonstrated increased iron levels on a consistent basis (Elkashef et al. 1994).

The metabolism of antipsychotics may contribute to EPS. Haloperidol, when given intravenously, has a much lower incidence of EPS than when it is used orally or intramuscularly, even when given at extremely high doses. Haloperidol is metabolized to reduced haloperidol in the liver. When administered intravenously, haloperidol enters the central nervous system (CNS) before metabolites are produced. It has been proposed that dopamine$_2$ (D_2) receptor saturation by haloperidol, rather than by reduced haloperidol, could account for the difference in EPS production (Menza et al. 1987).

More recent investigations of clozapine and other novel antipsychotics have focused on dopamine and serotonin (5-HT) receptors (Kapur and Remington 1996). Clozapine, olanzapine, quetiapine, risperidone, and ziprasidone are potent serotonin$_{2A}$ (5-HT_{2A}) receptor antagonists and relatively weaker D_2 antagonists, compared with typical antipsychotics. They all have a reduced EPS profile, compared with typical antipsychotics (Meltzer 1999).

Typical antipsychotics initially increase dopamine synthesis, turnover, and release in the striatum of baboons (Meldrum et al. 1977). This increased dopamine production reaches a maximum 1–5 hours after a single neuroleptic injection, which corresponds in time with the development of ADRs in baboons. During chronic treatment (up to 11 days), there is a marked diminution in the capacity of the antipsychotics to provoke an increased turnover of dopamine. Chronic haloperidol treatment causes decreased striatal dopaminergic neurotransmission and upregulation of postsynaptic D_2 receptors (Ichikawa and Meltzer 1991). In contrast, chronic clozapine treatment causes a slight *increase* in striatal dopaminergic neurotransmission and no changes in D_2 receptors. This has recently also been demonstrated in humans (Silvestri et al. 2000). These differences may partly explain the lack of occurrence of EPS and TD with clozapine and perhaps also with the other novel antipsychotics.

Dopamine$_1$ (D_1) receptor antagonists have a lower EPS potential than do traditional D_2 antipsychotics in nonhuman primates (Coffin et al. 1989). Patients who were clinical responders to antipsychotics and who had lower D_2 receptor occupancy by positron emission tomography (PET) analysis were found to have a lower incidence of EPS. Patients treated with clozapine had lower D_2 receptor occupancy than patients treated with typical antipsychotics (Farde et al. 1992). The balanced D_1/D_2 receptor function may prevent development of EPS and TD (Gerlach and Hansen 1992).

The rate of dissociation from the D_2 receptor may be as important as the degree of D_2 blockade, with regard to EPS. Novel antipsychotics have a faster dissociation rate from the D_2 receptor than do traditional antipsychotics (Kapur and Seeman 2001).

The high ratio of serotonin$_2$ (5-HT$_2$) receptor blockade to striatal D_2 receptor blockade that occurs with clozapine may account for clozapine's lack of EPS (Meltzer et al. 1989). Evidence suggests that decreasing serotonergic neurotransmission reverses or prevents catalepsy induced by D_2 receptor blockade (Meltzer and Nash 1991).

Clozapine also has a high affinity for dopamine$_3$ (D_3) and dopamine$_4$ (D_4) receptors (Sokoloff et al. 1990; Van Tol et al. 1991). The binding of clozapine to these receptors has also been proposed as a possible mechanism involved in the favorable EPS profile of clozapine.

Rating

Investigations of treatment for EPS led to the need to develop instruments to evaluate and quantify them. An initial EPS scale was shown to have both clinical validity and high interrater reliability, but it did not adequately assess salivation and tremor (G. M. Simpson et al. 1964). Scores were low, despite obvious and disabling tremor or salivation that required treatment with antiparkinson medication. Subsequently, the scale was expanded to 10 items (rated on a five-point scale), including tremor and salivation (G. M. Simpson and Angus 1970). This scale has good psychometric properties and is simple to use and score. It has been modified for outpatient use by eliminating the leg rigidity item and by replacing head dropping with head rotation. Studies using this scale have shown that scores correlate with the dosages and plasma levels of an antipsychotic. The scale is widely used in clinical trials and can be completed by nurses for the routine monitoring of neuroleptic treatment.

The Simpson-Angus Scale does not include a direct rating for bradykinesia or akinesia. Mindham (1976) modified the scale to include an item for lack of facial expression. Additional rating scales for EPS have since been developed, including the Chouinard Extrapyramidal Rating Scale (Chouinard et al. 1980), Targeting of Abnormal Kinetic Effects (TAKE) Scale (Wojcik et al. 1980), St. Hans Rating Scale for Extrapyramidal Syndromes (Gerlach et al. 1993), and Dyskinesia Identification System Condensed User Scale (DISCUS; Kalachnik and Sprague 1993).

The Modified Simpson-Angus Scale includes a single item for rating akathisia. More comprehensive scales have been devised specifically to rate akathisia, including the Barnes Akathisia Rating Scale (Barnes 1989), Hillside Akathisia Scale (Fleischhacker et al. 1989), and Prince Henry Hospital Akathisia Rating Scale (PHH Scale; Sachdev 1994).

Scales have also been developed for the assessment of dyskinetic movements. These include the Abnormal Involuntary Movement Scale (AIMS; Guy 1976) and the Simpson/Rockland Scale (G. M. Simpson et al. 1979).

Instrumental devices have been developed for the assessment of EPS, and several have been shown to correlate with clinical scales (Büchel et al. 1995). Instrumental devices have the advantage of increased reliability of quantitative measures, primarily through the elimination of subjective error associated with clinical raters; however, instrumental devices also have disadvantages. They often require greater patient cooperation than do clinical scales. They may require physical contact with the subject, which can affect measurements. They often evaluate a limited area, unlike clinical scales, which evaluate a patient in multiple areas as well as globally. As of this writing, clinical scales generally can be considered to have better global clinical validity with greater ease of use, while instrumental measures provide greater reliability (Büchel et al. 1995).

Trihexyphenidyl, a synthetic analogue of atropine, was introduced as benzhexol hydrochloride in 1949. It was found to be effective in the treatment of Parkinson's disease in a study of 411 patients (Doshay et al. 1954). Thereafter, it was also used to treat neuroleptic-induced parkinsonism (NIP) (Rashkis and Smarr 1957).

Structure–Activity Relations

Trihexyphenidyl, a tertiary-amine analogue of atropine, is a competitive antagonist of acetylcholine and other muscarinic agonists that compete for a common binding site on muscarinic receptors (Yamamura and Snyder 1974). It exerts little blockade at nicotinic receptors (Timberlake et al. 1961). Trihexyphenidyl and all drugs in this class are referred to as anticholinergic, antimuscarinic, or atropine-like drugs. As a tertiary amine, it readily crosses the blood–brain barrier (Brown and Taylor 1996).

Pharmacological Profile

The pharmacological properties of trihexyphenidyl are qualitatively similar to those of atropine and other anticholinergic drugs, although trihexyphenidyl acts primarily centrally, with few peripheral effects and little sedation. In the eye, anticholinergic drugs block both the sphincter muscle of the iris, causing the pupil to dilate (mydriasis), and the ciliary muscle of the lens, preventing accommodation and causing cycloplegia. In the heart, anticholinergic drugs usually produce a mild tachycardia through vagal blockade at the sinoatrial node pacemaker, although a mild slowing can occur. In the gastrointestinal tract, anticholinergic drugs reduce gut motility and salivary and gastric secretions. Salivary secretion is particularly sensitive and can be completely abolished. In the respiratory system, anticholinergic agents reduce secretions and can produce mild bronchodilatation. Anticholinergics inhibit the activity of sweat glands and mildly decrease contractions in the urinary and biliary tracts (Brown and Taylor 1996).

Pharmacokinetics and Disposition

Peak concentration for trihexyphenidyl is reached 1–2 hours after oral administration, and its half-life is 10–12 hours (Cedarbaum and McDowell 1987). As a tertiary amine, it crosses the blood–brain barrier to enter the CNS.

Mechanism of Action

The presumed mechanism of action of trihexyphenidyl for treatment of EPS is the blockade of intrastriatal cholinergic activity, which is relatively increased, compared with nigrostriatal dopaminergic activity, which has become decreased by antipsychotic blockade. The blockade of cholinergic activity returns the system to its previous equilibrium.

Indications and Efficacy

Anticholinergic agents were reported to have been effective treatment for NIP from open empirical trials (Medina et al. 1962; Rashkis and Smarr 1957). Eventually, controlled trials were conducted, with most involving comparisons only with different anticholinergics and not with placebo. Despite the limited evidence of efficacy against placebo, anticholinergic agents became the mainstay of treatment for NIP, and they remain so today.

Trihexyphenidyl has U.S. Food and Drug Administration (FDA) approval for treatment of all forms of parkinsonism, including NIP. Daily doses of 5–30 mg have been used in studies of trihexyphenidyl in the treatment of Parkinson's disease and NIP. Much higher dosages (up to 75 mg/day) have been used for the treatment of primary dystonia. However, the benefits of high doses have been limited by the adverse effects on cognition and memory (Jabbari et al. 1989; Taylor et al. 1991). Side effects correlate with blood levels, but efficacy does not (Burke and Fahn 1985). The individual therapeutic dose must be determined empirically and can vary widely.

Side Effects and Toxicology

Peripheral side effects

The peripheral side effects of trihexyphenidyl result from parasympathetic muscarinic blockade, and they occur in a consistent hierarchy among different organs. They are qualitatively similar to the side effects of atropine and other anticholinergic drugs, but they are quantitatively less because of the reduced peripheral activity of trihexyphenidyl (Brown 1990).

Anticholinergic drugs initially depress salivary and bronchial secretions and sweat production. Reduced salivation produces dry mouth and contributes to the high incidence of dental caries among patients with chronic psychiatric problems (Winer and Bahn 1967). Treatment for this condition is unsatisfactory, and chewing sugar-free gum or sucking on hard candy is limited by the need for

constant use. Reduced sweating can contribute to heat prostration and heat stroke, particularly in warmer ambient temperatures. The next physiological effects occur in the eyes and heart. Pupillary dilatation and inhibition of accommodation in the eye lead to photophobia and blurred vision. Attacks of acute glaucoma can occur in susceptible subjects with narrow-angle glaucoma, although this is relatively uncommon. Vagus nerve blockade leads to increased heart rate and is more apparent in patients with high vagal tone (usually younger males). The next effects are inhibition of urinary bladder function and bowel motility, which can produce urinary retention, constipation, and obstipation. Sufficiently high doses of anticholinergics will inhibit gastric secretion and motility (Brown and Taylor 1996).

Central side effects

Memory disturbance is the most common central side effect of anticholinergic medications because memory is dependent on the cholinergic system (Drachman 1977). Patients with underlying brain pathology are more susceptible to memory disturbance (Fayen et al. 1988). Patients with chronic psychiatric conditions often have a decreased ability to express themselves, making evaluation of memory more difficult; therefore, subtle memory changes can be missed or attributed to the underlying illness. Memory disturbances have been identified in patients with Parkinson's disease treated with anticholinergics (Yahr and Duvoisin 1968), even in some patients receiving only small doses (Stephens 1967). Patients receiving an antipsychotic and benztropine demonstrated significantly increased overall scores on the Wechsler Memory Scale when benztropine was withdrawn (Baker et al. 1983).

Anticholinergic toxicity produces restlessness, irritability, disorientation, hallucinations, and delirium. Elderly patients are at increased risk for both memory loss and toxic delirium, even at very low anticholinergic doses, because of the natural loss of cholinergic neurons with aging (Perry et al. 1977). Toxic doses can produce a clinical situation identical to atropine poisoning, including fixed dilated pupils, flushed face, sinus tachycardia, urinary retention, dry mouth, and fever. This condition can proceed to coma, cardiorespiratory collapse, and death.

Drug–Drug Interactions

There may be increased anticholinergic effects, including side effects, when trihexyphenidyl or any anticholinergic is combined with amantadine. Anticholinergic side effects are also much more likely to occur when drugs with anticholinergic properties are combined.

Anticholinergic effect on antipsychotic blood levels

Some investigators have suggested that anticholinergic medications can affect antipsychotic blood levels. However, a review of this subject suggests that the available data are too limited to reach a definite conclusion on this matter. The best studies indicate that anticholinergic drugs do not affect antipsychotic blood levels or, at most, that they lower these levels only transiently (McEvoy 1983).

Anticholinergic effect on antipsychotic activity

Haase and Janssen (1965) reported from open studies that when anticholinergic drugs are added to antipsychotic drugs given at the neuroleptic threshold, rigidity, hypokinesia, and therapeutic effects disappear but psychopathology worsens. Other studies have demonstrated no change or an improvement in scores of psychopathology, with the addition of anticholinergics (Hanlon et al. 1966; G. M. Simpson et al. 1980).

Anticholinergic Abuse

Anticholinergic drugs may be abused for their euphoriant and hallucinogenic effects, and they may be combined with street drugs for enhanced effect (Crawshaw and Mullen 1984). Patients with a history of substance abuse are more likely to abuse anticholinergics (Wells et al. 1989). Cases of abuse have

been reported with all anticholinergics, but trihexyphenidyl apparently is the anticholinergic most likely to be abused (MacVicar 1977). Theoretically, one anticholinergic should be as effective as another, although an idiosyncratic response is possible. The potential for abuse needs to be considered, particularly in patients with a history of substance abuse.

Benztropine

History and Discovery

Benztropine was synthesized by uniting the tropine portion of atropine with the benzhydryl portion of diphenhydramine hydrochloride. Benztropine was found to be effective in the treatment of 302 patients with Parkinson's disease (Doshay 1956). The best results in the control of rigidity, contracture, and tremor were obtained at doses of 1–4 mg qd for older patients and 2–8 mg qd for younger ones. Doses of 15–30 mg qd caused excessive flaccidity in some patients, who became unable to lift their arms or raise their heads off the bed. Subsequently, benztropine was found to be effective for the treatment of NIP (Karn and Kasper 1959).

Structure–Activity Relations

Benztropine is a tertiary amine with activity similar to that of trihexyphenidyl, and as a tertiary amine, it enters the CNS.

Pharmacological Profile

Benztropine has the pharmacological properties of an anticholinergic and an antihistaminic; however, it produces less sedation (in experimental animals) than does diphenhydramine.

Pharmacokinetics and Disposition

Little is known about the pharmacokinetics of benztropine. A correlation between serum anticholinergic levels and the presence of EPS has been demonstrated (Tune and Coyle 1980). There is little correlation between the total daily dose of benztropine and the serum anticholinergic level, with the serum activity for a given dose varying 100-fold between subjects. When treated with increased doses of anticholinergics, patients with EPS demonstrated increased serum anticholinergic activity and decreased EPS. Relatively small increments in the oral dose of an anticholinergic drug can result in significant nonlinear increases in serum anticholinergic activity levels. Benztropine has a long-acting effect and can be given once or twice a day.

Indications and Efficacy

Benztropine has FDA approval for the treatment of all forms of parkinsonism, including NIP. Total daily doses of 1–8 mg have generally been used to treat NIP.

Mechanism of Action, Side Effects, and Drug–Drug Interactions

The mechanisms of action and the drug interactions for benztropine are similar to those of trihexyphenidyl. The side effects of these two drugs are also similar, but the degree of sedation produced by benztropine may be less (Doshay 1956). Although not yet confirmed in double-blind studies, this reported difference in sedation might account for the fact that trihexyphenidyl is reportedly the anticholinergic drug more likely to be abused.

Biperiden

Biperiden is an analogue of trihexyphenidyl that has greater peripheral anticholinergic activity than trihexyphenidyl and greater activity against nicotinic receptors (Timberlake et al. 1961). Biperiden is well absorbed from the gastrointestinal tract. Its metabolism, though not completely understood, involves hydroxylation in the liver. Its activity, pharmacological profile, and side effects are similar to

those of other anticholinergics. It has FDA approval for use in the treatment of all forms of parkinsonism, including NIP. Total daily doses of 2–24 mg have been used in studies of biperiden for the treatment of parkinsonism and NIP.

Procyclidine

Procyclidine is an analogue of trihexyphenidyl (Schwab and Chafetz 1955). Its activity, pharmacology, and side effects are similar to those of other anticholinergics. There is little information about its pharmacokinetics. Procyclidine has FDA approval for use in treating all forms of parkinsonism, including NIP. Total daily doses of 5–30 mg have been used in studies of procyclidine for the treatment of parkinsonism and NIP.

ANTIHISTAMINIC MEDICATIONS

Diphenhydramine

History and Discovery

Antihistaminic agents have been used for the treatment of Parkinson's disease. Diphenhydramine, one of the first antihistamines developed and used clinically (Bovet 1950), has been the primary antihistamine studied in the treatment of EPS. Although some antihistamines may be effective, other antihistamines have not been systematically studied for the treatment of EPS.

Structure–Activity Relations

All drugs referred to as antihistamines are reversible competitive inhibitors of histamine at the H_1 receptor. Some antihistamines also inhibit the action of acetylcholine at the muscarinic receptor. It is believed that central muscarinic blockade, rather than histaminic blockade, is responsible for the therapeutic effect of antihistamines for EPS. Ethanolamine antihistamines (diphenhydramine, dimenhydrinate, and carbinoxamine maleate) have the greatest anticholinergic activity, and ethylenediamine antihistamines have the least anticholinergic activity. Antihistamines such as terfenadine and astemizole have no anticholinergic activity, while many of the remaining antihistamines have very mild anticholinergic activity (Babe and Serafin 1996).

Pharmacological Profile

Antihistamines inhibit the constrictor action of histamine on respiratory smooth muscle. They restrict the vasoconstrictor and vasodilatory effects of histamine on vascular smooth muscle and block histamine-induced capillary permeability. Antihistamines with CNS activity are depressants, producing diminished alertness, slowed reaction times, and somnolence. They can also block motion sickness. Antihistaminic drugs with anticholinergic activity also possess mild antimuscarinic pharmacological properties similar to those of other atropine-like drugs (Babe and Serafin 1996).

Pharmacokinetics and Disposition

Diphenhydramine is well absorbed from the gastrointestinal tract. Peak concentrations occur 2–3 hours after oral administration. Its therapeutic effects usually last 4–6 hours, and it has a half-life of 3–9 hours. Diphenhydramine is widely distributed throughout the body, and as a tertiary amine, it enters the CNS. Age does not affect its pharmacokinetics. It undergoes demethylations in the liver and is then oxidized to carboxylic acid (Paton and Webster 1985).

Mechanism of Action

Diphenhydramine possesses some anticholinergic activity, which is believed to be the basis for its effect in diminishing EPS.

Indications and Efficacy

Diphenhydramine has FDA approval for parkinsonism, including NIP, in the elderly and for mild cases in other age groups. It is probably not as efficacious for treating EPS as are pure anticholinergic drugs, but it may be better tolerated in patients bothered by anticholinergic side effects, such as geriatric patients. Diphenhydramine also tends to be more sedating than anticholinergics, which can also be beneficial for some patients. The dosage generally ranges from 50 to 400 mg/day, given in divided doses.

Diphenhydramine also has indications for multiple other conditions that are unrelated to EPS.

Side Effects and Toxicology

The primary side effect of diphenhydramine is sedation. Although other antihistamines may cause gastrointestinal distress, diphenhydramine has a low incidence of such an effect. Drying of the mouth and respiratory passages can occur. In general, the toxic effects are similar to those of trihexyphenidyl and of other anticholinergics.

Drug–Drug Interactions

Diphenhydramine has no reported interactions with other drugs, but it has an additive depressant effect when used in combination with alcohol or with other CNS depressants.

DOPAMINERGIC MEDICATIONS

Amantadine

History and Discovery

Anticholinergic side effects and inadequate treatment response eventually led to the investigation of other agents to treat EPS. Initially, both methylphenidate and intravenous caffeine were investigated as treatments for NIP. Neither agent achieved general use, despite apparent efficacy (Brooks 1956; Freyhan 1959).

Amantadine is an antiviral agent that is effective against A2 (Asian) influenza (Wingfield et al. 1969). It was unexpectedly found to produce symptomatic improvement in patients with Parkinson's disease (Parkes et al. 1970; Schwab et al. 1969), and soon thereafter, it was reported to be effective for NIP (Kelly and Abuzzahab 1971).

Structure–Activity Relations

Amantadine is a water-soluble tricyclic amine. It binds to the M2 protein, a membrane protein that functions as an ion channel on the influenza A virus (Hay 1992). Its activity in reducing EPS is not known, although it has been shown to have activity at glutamate receptors (Stoof et al. 1992).

Pharmacological Profile

Amantadine is effective in preventing and treating illness from influenza A virus. It also reduces the symptoms of parkinsonism.

Pharmacokinetics and Disposition

In young healthy subjects, amantadine is slowly and well absorbed from the gastrointestinal tract, with unchanged oral bioavailability over the dose range of 50–300 mg. It reaches steady state in 4–7 days. Plasma concentrations (0.12–1.12 μg/mL) may have some correlation with improvement in EPS (Greenblatt et al. 1977; Pacifici et al. 1976). Amantadine has relatively constant blood levels and a long duration of action (Aoki et al. 1979) and is excreted unchanged by the kidneys. Its half-life for elimination is about 16 hours, which is prolonged in elderly patients and in patients with impaired renal function (Hayden et al. 1985).

Mechanism of Action

Amantadine inhibits viral replication by binding to the M2 protein on the viral membrane and inhibiting replication (Hay 1992). Its mechanism of action as an antiparkinson agent is less clear. It has no anticholinergic activity in tests on animals, being only 1/209,000th as potent as atropine (Grelak et al. 1970). It appears to cause the release of dopamine and other catecholamines from intraneuronal storage sites in an amphetamine-like mechanism. It has also been shown to have activity at glutamate receptors, which may contribute to its antiparkinsonian effect (Stoof et al. 1992). Amantadine has preferential selectivity for central catecholamine neurons (Grelak et al. 1970; Strömberg et al. 1970).

Indications and Efficacy

Amantadine has undergone more extensive investigation than have anticholinergic agents with regard to the efficacy of EPS. Most studies, though not all, found amantadine to be equal in efficacy to benztropine or biperiden in the treatment of parkinsonism (DiMascio et al. 1976; Fann and Lake 1976; Konig et al. 1996; Silver et al. 1995; Stenson et al. 1976). Some studies found amantadine to be more effective than benztropine (Merrick and Schmitt 1973) or effective for EPS that are refractory to benztropine (Gelenberg 1978). However, other studies found that amantadine was inferior to benztropine (Kelly et al. 1974), no more effective than placebo (Mindham et al. 1972), or unable to control EPS when used to replace an anticholinergic agent (McEvoy et al. 1987). The varying results can be attributed to differing methodologies and patient populations. The conclusion that can be drawn from these studies is that amantadine is an effective drug for treating parkinsonism but that there are no clear data to support its use prior to using anticholinergic agents. Most of the studies were of short duration, and in patients with Parkinson's disease, amantadine appears to lose efficacy after several weeks (Mawdsley et al. 1972; Schwab et al. 1972). Similar studies evaluating the long-term efficacy of amantadine have not been conducted for EPS.

Amantadine has also been evaluated for the treatment of akathisia, but in only a small number of patients. The conclusion from these studies is that amantadine is probably not effective for treating akathisia (Fleischhacker et al. 1990).

Amantadine has FDA approval for the treatment of NIP and Parkinson's disease/syndrome, as well as for the treatment and prophylaxis of influenza A respiratory illness. Dosages of 100–300 mg/day are used for the treatment of NIP, and plasma concentrations may have some correlation with improvement.

Side Effects and Toxicology

At dosages of 100–300 mg/day, amantadine does not produce adverse effects as readily as do anticholinergic medications. Side effects of amantadine result from CNS stimulation, with symptoms including irritability, tremor, dysarthria, ataxia, vertigo, agitation, reduced concentration, hallucinations, and delirium (Postma and Tilburg 1975). Hallucinations are often visual. Side effects are more likely to occur in elderly patients and in patients with reduced renal function (Borison 1979; Ing et al. 1979). Toxic effects are directly related to elevated amantadine serum levels (>1.5 μg/mL). Resolution of toxic symptoms is dependent on renal clearance and may require dialysis in extreme cases, although less than 5% of amantadine is removed by dialysis.

Patients with congestive heart failure or peripheral edema should be monitored because of amantadine's ability to increase the availability of catecholamines. Long-term use of amantadine may produce livedo reticularis in the lower extremities from the local release of catecholamines and resulting vasoconstriction (Cedarbaum and Schleifer 1990). Amantadine should be used with caution in patients with seizures because of possible increased seizure activity. Amantadine is embryotoxic and teratogenic in animals, but there are no well-controlled studies in women regarding teratogenicity.

Drug–Drug Interactions

There are no reported interactions between amantadine and other drugs. There may be increased anticholinergic side effects when amantadine is used in combination with an anticholinergic agent.

β-Adrenergic Receptor Antagonists

History and Discovery

Propranolol was reported to be effective for the treatment of restless legs syndrome (Ekbom's syndrome; Ekbom 1965), which resembles the physical movements of akathisia (Strang 1967). Later it was reported to be effective in the treatment of neuroleptic-induced akathisia (Kulik and Wilbur 1983; Lipinski et al. 1983). Subsequently, other β-blockers have also been investigated for the treatment of akathisia.

Structure–Activity Relations

Competitive β-adrenergic receptor antagonism is the property common to all β-blockers. β-Blockers are distinguished by the additional properties of their relative affinity for β_1 and β_2 receptors (selectivity), lipid solubility, intrinsic β-adrenergic receptor *agonist* activity, blockade of β receptors, capacity to induce vasodilation, and general pharmacokinetic properties (Hoffman and Lefkowitz 1996). β-Blockers with high lipid solubility readily cross the blood–brain barrier.

Pharmacological Profile

The major pharmacological effects of β-blockers involve the cardiovascular system. β-Blockers slow the heart rate and decrease cardiac contractility; however, these effects are modest in a normal heart. In the lung, they can cause bronchospasm, although, again, there is little effect in normal lungs. They block glycogenolysis, preventing production of glucose during hypoglycemia (Hoffman and Lefkowitz 1996). β-Blockers affect lipid metabolism by preventing release of free fatty acids while elevating triglycerides (N. E. Miller 1987). In the CNS, they produce fatigue, sleep disturbance (insomnia and nightmares), and CNS depression (see Drayer 1987; Gengo et al. 1987).

Pharmacokinetics and Disposition

All β-blockers, except atenolol and nadolol, are well absorbed from the gastrointestinal tract (McDevitt 1987). All β-blockers undergo metabolism in the liver. Propranolol and metoprolol undergo significant first-pass effect, with bioavailability as low as 25%. Large interindividual variation (as much as 20-fold) leads to wide variation in clinically therapeutic doses (Hoffman and Lefkowitz 1996). Metabolites appear to have limited β-receptor antagonistic activity. The degree to which a particular β-blocker enters the CNS is related directly to its lipid solubility (Table 34–2).

Mechanism of Action

The exact mechanism of action of β-blockers in the treatment of EPS is unclear. The existence of a noradrenergic pathway from the locus coeruleus to the limbic system has been proposed as a modulator involved in symptoms of TD, akathisia, and tremor (Wilbur et al. 1988). It appears that lipid solubility and the corresponding ability to enter the CNS are the most important factors determining the efficacy of a β-blocker in treating akathisia and perhaps other types of EPS (Adler et al. 1991).

Indications and Efficacy

β-Blockers have FDA approval primarily for cardiovascular indications, and propranolol is also indicated for familial essential tremor, but there are no FDA-approved indications for the treatment of any type of EPS.

β-Blockers have been studied primarily for the treatment of akathisia. Both nonselective (β_1 and β_2 antagonism) and selective (β_1 antagonism) β-blockers have been reported to be efficacious. The studies have generally been for short periods of time, involving small numbers of patients who were often receiving varying combinations of additional antiparkinsonian agents or benzodiazepines to which β-blockers had been added (Fleischhacker et al. 1990). From these studies, it is difficult to draw any firm conclusions, but β-blockers probably have some efficacy in the treatment of akathisia. The maximum benefit for propranolol occurred at 5 days (Fleischhacker et al. 1990). Betaxolol may be the β-blocker of choice in patients with lung disease and smokers because of its β_1 selectivity at lower dosages (5–10 mg/day).

In addition to essential tremor, β-blockers have also been reported to be beneficial for the tremor of Parkinson's disease (Foster et al. 1984) and lithium-induced tremor (Gelenberg and Jefferson 1995). However, for neuroleptic-induced tremor, propranolol was found to be not any better than placebo (Metzer et al. 1993), which could be an indication of a difference in etiologies for the different tremors.

Side Effects and Toxicology

The side effects of β-blockers result from β receptor blockade. β_2 Blockade of bronchial smooth muscle produces bronchospasm. Individuals with normal lung function are unlikely to be affected, but smokers and others with lung disease can develop serious breathing difficulties. β-Blockers can contribute to heart failure in susceptible individuals, such as those with compensated heart failure, acute myocardial infarction, or cardiomegaly. Abrupt cessation of β-blockers can also exacerbate coronary heart disease in susceptible patients, producing angina or, potentially, myocardial infarction (for details, see Hoffman and Lefkowitz 1996).

In individuals with normal heart function, bradycardia produced by β-blockers is insignificant; however, in patients with conduction defects or when combined with other drugs that impair cardiac conduction, β-blockers can contribute to serious conduction problems.

β-Blockers can block the tachycardia associated with hypoglycemia, eliminating this warning sign in patients with diabetes. β_2 Blockade also can inhibit glycogenolysis and glucose mobilization, interfering with recovery from hypoglycemia (Hoffman and Lefkowitz 1996).

β-Blockers can impair exercise performance and produce fatigue, insomnia, and major depression. However, the development of major depression probably only occurs in individuals with a predisposition to developing depression.

Drug–Drug Interactions

β-Blockers can have significant interactions with other drugs. Chlorpromazine in combination with propranolol may increase the blood levels of both drugs. Additive effects on cardiac conduction and blood pressure can occur when β-blockers are combined with drugs having similar effects (e.g., calcium channel blockers). Phenytoin, phenobarbital, and rifampin increase the clearance of propranolol. Cimetidine increases propranolol blood levels by decreasing hepatic metabolism. Theophylline clearance is reduced by propranolol. Aluminum salts (antacids), cholestyramine, and colestipol may reduce the absorption of β-blockers (Hoffman and Lefkowitz 1996).

BENZODIAZEPINES

History and Discovery

Diazepam was initially shown to be effective in the treatment of restless legs syndrome (Ekbom's syndrome), which resembles the physical movements of akathisia (Ekbom 1965). Subsequently, diazepam, lorazepam, and clonazepam were reported to be beneficial for neuroleptic-induced akathisia (Adler et al. 1985; Donlon 1973; Kutcher et al. 1987). Clonazepam has also been reported to be beneficial for drug-induced dystonia (O'Flanagan 1975) and TD (Thaker et al. 1987).

Mechanism of Action

All benzodiazepines promote the binding of GABA to $GABA_A$ receptors, magnifying the effects of GABA. The mechanism of action regarding improvement of EPS is unknown, but it may be related to the augmentation of inhibitory GABAergic effect (Hobbs et al. 1996). For a complete discussion of the properties of benzodiazepines, see Chapter 24.

Indications and Efficacy

Benzodiazepines have FDA approval for their use in treating anxiety disorders, agoraphobia, insomnia, management of alcohol withdrawal, anesthetic premedication, seizure disorders, and skeletal muscle relaxation; however, there is no approval for its use in treating any type of EPS. As noted above, a few initial reports have indicated that benzodiazepines are beneficial for the treatment of akathisia. Other studies have also reported similar benefit (Bartels et al. 1987; Braude et al. 1983; Gagrat et al. 1978; Horiguchi and Nishimatsu 1992; Kutcher et al. 1989; Pujalte et al. 1994).

Clonazepam has also been reported to be effective in the treatment of TD (Bobruff et al. 1981; Thaker et al. 1990). Doses of 1–10 mg were used in the first study, although the optimal dosage was found to be 4 mg/day, with many patients unable to tolerate higher dosages. In the second study, dosages of 2–4.5 mg/day were used, and tolerance developed after 5–8 months.

Although some of the studies were limited by short duration and by the small number of subjects also receiving other antiparkinsonian agents, the overall conclusion was that benzodiazepines probably have some efficacy in the treatment of akathisia and TD. However, the potential problems associated with the chronic use of benzodiazepines (i.e., tolerance and abuse) need to be kept in mind.

Lorazepam (intermediate-acting) and clonazepam (long-acting) are the two primary benzodiazepines that have been studied in the treatment of EPS. Because of its long duration of action, clonazepam can often be given once a day. Lorazepam has the advantage of having no active metabolites, which eliminates potential side effects and toxicity.

BOTULINUM TOXIN

History and Discovery

Botulinum toxin, produced by *Clostridium botulinum,* causes botulism when ingested. The first clinical use of the toxin was in the treatment of childhood strabismus (Scott 1980). The first focal dystonia treated was blepharospasm (Elston 1988). Botulinum toxin has been subsequently used to treat a number of other conditions associated with excessive muscle activity, including neuroleptic-induced dystonias (Hughes 1994).

Structure–Activity Relations

There are seven immunologically distinct botulinum toxins (L. L. Simpson 1981). Type A is the primary type used clinically (Hambleton 1992). Type F and possibly type B also have clinical utility, but they have much shorter durations of action (≤3 weeks, compared with ≥3 months for type A) (Borodic et al. 1996). The toxin is quantified by bioassay and is expressed as mouse units, which refers to the dose that is lethal to 50% of animals following intraperitoneal injection (Quinn and Hallet 1989).

Pharmacological Profile

Botulinum toxin binds to cholinergic motor nerve terminals, preventing release of acetylcholine and producing a functionally denervated muscle. The prevention of acetylcholine release occurs within a few hours, but the clinical effect does not occur for 1–3 days. The innervation gradually becomes restored, although the number and/or size of active muscle fibers is reduced (Odergren et al. 1994).

Pharmacokinetics and Disposition

After binding to the presynaptic nerve terminal, the toxin is taken into the nerve cell and is metabolized. When antibodies are present, the toxin is metabolized by immunological processes.

Mechanism of Action

Botulinum toxin acts presynaptically to prevent the release of acetylcholine at the neuromuscular junction. This produces a functional chemical denervation and paralysis of the muscle. When botulinum toxin is used clinically, the aim is to reduce the excessive muscle activity without producing significant weakness (Hughes 1994).

Indications and Efficacy

The FDA has approved the use of botulinum toxin for strabismus, blepharospasm, and other facial nerve disorders (see Jankovic and Brin 1991). Botulinum toxin has been used to treat focal neuroleptic-induced dystonias that may occur as part of TD, including laryngeal dystonia (Blitzer and Brin 1991) and refractory torticollis (Kaufman 1994). For laryngeal dystonia, the toxin is injected percutaneously through the cricothyroid membrane into the thyroarytenoid muscle bilaterally. The response rate is 80%–90%, and the effect lasts 3–4 months and sometimes longer. Botulinum treatment of tardive cervical dystonia has been found to be effective; the observed improvement is similar to the improvement seen in the treatment of idiopathic cervical dystonia, although patients with tardive cervical dystonia required higher doses (Brashear et al. 1998).

Side Effects and Toxicology

The major potential side effect of botulinum toxin is focal weakness in the muscle group injected—an effect that is usually dose dependent. This effect is generally temporary, given the mechanism of action. Transient weakness can occur through diffusion of the toxin into surrounding noninjected muscles (Hughes 1994).

Antibodies to the toxin can occur and thus can prevent a therapeutic response, particularly during subsequent treatments. The two main factors that apparently contribute to the development of antibodies are receiving a dose of the toxin for the first time at an early age and total cumulative dose (Jankovic and Schwartz 1995). Some patients with antibodies will respond to other botulinum

serotypes, such as type F (Greene and Fahn 1993). Local skin reactions can also occur. Some degree of muscle atrophy is apparent in injected muscles (Hughes 1994). Reinnervation usually takes place over the course of 3–4 months (Odergren et al. 1994).

There are no known contraindications. Because the effect on the fetus is unknown, use of the toxin is not recommended during pregnancy. In conditions in which there are neuromuscular junction disorders, such as myasthenia gravis, patients could theoretically experience increased weakness. The long-term effects are unknown (Hughes 1994).

Drug–Drug Interactions

There are no known interactions of botulinum toxin with other drugs.

VITAMIN E (α-TOCOPHEROL)

History and Discovery

The existence of vitamin E was postulated in 1922, at which time it appeared that rats required an unknown dietary supplement to sustain pregnancy. That supplement, vitamin E (α-tocopherol), was eventually isolated from wheat germ oil (Evans et al. 1936). Vitamin E deficiency in animals leads to several specific diseases; however, in humans, there is little evidence of any specific metabolic effects or illnesses. Despite the paucity of evidence for its benefit, vitamin E has been used over the years to treat multiple conditions, including infertility, various menstrual disorders, neurological and muscular disorders, and anemias (Marcus and Coulston 1996).

Vitamin E was proposed as a treatment for TD after it was noted that a neurotoxin in rats induced an irreversible movement disorder and axonal damage similar to that caused by vitamin E deficiency. It was proposed that chronic neuroleptic use might produce free radicals, which would contribute to neurological damage and TD, and that the antioxidant effect of vitamin E could attenuate the damage (Cadet et al. 1986).

Pharmacological Profile

In humans, symptoms of vitamin E deficiency are not very common, and they almost always result from malabsorption (Bieri and Farrell 1976). The only consistent laboratory finding is that subjects with low serum vitamin E levels demonstrate increased hemolysis of erythrocytes exposed to oxidizing agents (Leonard and Losowsky 1967). In addition, patients with glucose-6-phosphate dehydrogenase deficiency may have improved erythrocyte survival when treated with large doses (Corash et al. 1980).

Side Effects and Toxicology

Side effects are minimal when vitamin E is given orally. High levels of vitamin E can exacerbate bleeding abnormalities that are associated with vitamin K deficiency. Dosages of up to 3,200 mg/day in studies for other conditions have been used without significant adverse effects (Kappus and Diplock 1992). The only known drug interactions are with vitamin K (when it is being given for a deficiency) and bleeding abnormalities and possibly with oral anticoagulants. High doses of vitamin E can exacerbate the coagulation abnormalities in both cases and therefore are contraindicated (Kappus and Diplock 1992).

Indications and Efficacy

The only known indication for vitamin E is treatment of vitamin E deficiency, which almost always results from malabsorption syndromes or abnormal transport, such as with abetalipoproteinemia. In most cases, other vitamins and nutrients are also deficient; therefore, symptoms may not be the result of only vitamin E deficiency. Supplementation in children has been shown to be effective for the neurological symptoms resulting from malabsorption and vitamin E deficiency in chronic cholestasis

(Sokol et al. 1993). Apparently, there is also a rare condition of spinocerebellar degeneration caused by deficiency without malabsorption (Sokol 1988).

Early studies of vitamin E treatment of TD demonstrated a range of results from general benefit (Adler et al. 1993; Dabiri et al. 1994; Lohr et al. 1988) to benefit only in subjects with TD of less than 5 years' duration (Egan et al. 1992; Lohr and Caligiuri 1996) to no benefit (Schmidt et al. 1991; Shriqui et al. 1992).

Subsequently, a major prospective randomized trial treated 158 subjects with TD for up to 2 years with d-vitamin E (1,600 IU/day) or placebo (Adler et al. 1999). There were no significant effects of vitamin E on total scores or subscale scores for the AIMS, on electromechanical measures of dyskinesia, or on scores for four other scales measuring dyskinesia. The authors concluded that there was no evidence for efficacy of vitamin E in the treatment of TD (Adler et al. 1999).The use of vitamin E supplementation is not without risk. A meta-analysis of high-dosage vitamin E supplementation trials showed a statistically significant relationship between vitamin E dosage and all-cause mortality, with increased risk of dosages greater than 150 IU/day (E. R. Miller et al. 2005). Given the lack the data demonstrating consistent effectiveness for TD, we do not recommend that vitamin E be used for this purpose.

TREATMENT OF EXTRAPYRAMIDAL SIDE EFFECTS

Acute Dystonic Reactions

Intramuscular anticholinergics are the treatment of choice for ADRs. Benztropine 2 mg or diphenhydramine 50–100 mg generally will produce complete resolution within 20–30 minutes, with a second dose repeated after 30 minutes if there is not a complete recovery. Benztropine has been shown to resolve ADRs in less time than diphenhydramine (Lee 1979). Starting a standing dose of an antiparkinsonian agent afterward is generally not necessary. ADRs do not recur, unless large doses of high-potency antipsychotics are being used or unless the dose is increased. A more complete discussion of prophylaxis is given below.

Parkinsonism and Akathisia

The initial steps in treatment of parkinsonism (Table 34–3) and of akathisia (referred to here as EPS) are identical: evaluating the dose and type of antipsychotic. It has been shown that an increase in dose beyond the neuroleptic threshold will not produce any greater therapeutic benefit but will increase EPS (Angus and Simpson 1970a; Baldessarini et al. 1988; McEvoy et al. 1991). It has also been demonstrated that EPS frequently can be eliminated with a reduction in dosage or a change to a lower-potency antipsychotic (Braude et al. 1983; Stratas et al. 1963).

TABLE 34–3. Treatment of parkinsonism

Step	Action
1	Reduce dose of antipsychotic, if clinically possible.
2	Substitute a lower-potency antipsychotic, or carry out step 8.
3	Add an anticholinergic agent.
4	Titrate anticholinergic to maximum dose tolerable.
5	Add amantadine in combination with anticholinergic or as a single agent.
6	Add a benzodiazepine or a β-blocker.
7	In severe cases of EPS, stop antipsychotic temporarily and repeat process, beginning with step 3.
8	Substitute antipsychotic with atypical antipsychotic or clozapine.

If this approach does not resolve EPS, or if a lower-potency antipsychotic cannot be substituted, the

addition of an anticholinergic drug is the next step. Maximum therapeutic response occurs in 3–10 days, with more severe EPS taking a longer time to respond (DiMascio et al. 1976; Fann and Lake 1976). The anticholinergic dose should be increased until EPS are alleviated or until an unacceptable degree of anticholinergic side effects is obtained. Akathisia frequently does not respond as well to anticholinergic medications and amantadine as do parkinsonism and ADRs (DiMascio et al. 1976). Akathisia is more likely to be responsive to anticholinergic agents if symptoms of parkinsonism are also present (Fleischhacker et al. 1990).

If EPS remain uncontrolled, amantadine can be either added to the regimen or substituted as a single agent. The next step would be the addition of a benzodiazepine or a β-blocker, although there are fewer data supporting both of these treatments.

In the case of severe EPS, the antipsychotic should be temporarily stopped, because severe EPS may be a risk factor for the development of neuroleptic malignant syndrome (Levinson and Simpson 1986).

Additional drugs have been studied or suggested as treatments for akathisia. The data supporting the use of amantadine for the treatment of akathisia are limited. Clonidine has been studied in a small number of patients, but its benefit was limited by sedation and hypotension (Fleischhacker et al. 1990). Sodium valproate was reported to have had no significant effect on akathisia and was found to increase parkinsonism (Friis et al. 1983).

Iron supplementation has been suggested as a possible treatment for akathisia (Blake et al. 1986). A review of this subject concluded that iron supplements would, at best, have no effect on akathisia but that they could potentially worsen the condition and promote further long-term damage (Gold and Lenox 1995). Iron supplementation therefore should not be considered a treatment for akathisia and should not be given indiscriminately.

Atypical Antipsychotics for Treatment of Parkinsonism and Akathisia

Patients treated with clozapine were found to have significantly less parkinsonism than patients treated with the combination of chlorpromazine and an antiparkinsonian agent (benztropine) (Kane et al. 1988). The prevalence and incidence of akathisia have also been shown to be less in patients treated with clozapine than in patients treated with typical antipsychotics (Chengappa et al. 1994; Kurz et al. 1995; Stanilla et al. 1995). Subsequently, the new atypical antipsychotics (risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole) have also been shown to produce less EPS than haloperidol. Paliperidone extended release was compared with placebo and found to have a comparable incidence of EPS.

At lower doses, risperidone usually does not produce significant parkinsonism, but unlike clozapine, it can produce significant parkinsonism at higher doses (Chouinard et al. 1993). In initial studies comparing risperidone with haloperidol, the extrapyramidal scores for patients receiving risperidone were not significantly different from the scores of patients receiving placebo at 6 mg qd. Risperidone can cause ADRs, and patients with severe EPS at baseline were more likely to develop EPS when treated with risperidone (G. M. Simpson and Lindenmayer 1997). Subsequent studies have confirmed a reduced level of EPS with risperidone, compared with haloperidol (Csernansky et al. 2002). In general, risperidone has also been shown to produce less akathisia than haloperidol (Wirshing et al. 1999).

Olanzapine has been shown to have an antipsychotic effect comparable to that of haloperidol while producing less dystonia, parkinsonism, and akathisia (Tollefson et al. 1997). The reduced incidence of EPS occurred across the entire therapeutic dosage range of 5–24 mg/day. Olanzapine has subsequently been shown to produce less parkinsonism and akathisia, compared with haloperidol, in patients with treatment-resistant schizophrenia (Breier and Hamilton 1999) and in patients with first-episode psychosis (Sanger et al. 1999). Olanzapine has also been shown to have similar rates of EPS

and akathisia, compared with chlorpromazine, but without the need for any antiparkinsonian drugs (see Conley et al. 1998).

Quetiapine has been found to have antipsychotic activity comparable to haloperidol at doses ranging from 150 to 750 mg/day while producing parkinsonism at a level similar to that produced by placebo across the entire dosage range (Arvanitis and Miller 1997; Small et al. 1997). For most patients, there were no significant changes in AIMS scores at baseline and in scores at the end of a 6-week period of treatment.

A double-blind, dose-ranging trial comparing ziprasidone with haloperidol found comparable antipsychotic effect at higher dosages of ziprasidone. Concomitant benztropine use at any time during the study was less frequent with the highest dosage (160 mg/day) of ziprasidone (15%) than with haloperidol (53%) (Goff et al. 1998). Studies of ziprasidone found no significant differences in baseline-to-endpoint mean changes in Simpson-Angus Scale and AIMS scores with placebo or ziprasidone (40–160 mg/day) (Keck et al. 2001).

Aripiprazole was found to be comparable to risperidone in antipsychotic effect while producing EPS comparable to those seen with placebo (Kane et al. 2002; Potkin et al. 2003).

The most recent antipsychotic to gain FDA approval in the United States is paliperidone extended release (ER). Paliperidone ER was found to have an incidence of EPS nearly comparable to placebo (7% vs. 3%) at a dosage range of 3–15 mg/day (Kramer et al. 2007).

A study comparing 150 patients who were treated with either risperidone or olanzapine found that a statistically significantly smaller percentage of patients treated with olanzapine (25.3%) required anticholinergic treatment than did patients treated with risperidone (45.3%) (Egdell et al. 2000). Another study involving 377 patients comparing risperidone with olanzapine found EPS to be similar in both groups (24% and 20%, respectively) and of low severity (Conley and Mahmoud 2001).

Comparisons between clozapine and risperidone have found a reduced incidence of EPS for clozapine (Azorin et al. 2001). A study comparing the incidence of EPS produced by clozapine, risperidone, and typical antipsychotics found a hierarchy in the production of EPS, with clozapine producing the fewest EPS, followed by risperidone and then the typical antipsychotics (C. H. Miller et al. 1998).

In general, the novel antipsychotics have a reduced incidence of EPS compared with high-potency typical antipsychotics. Data from the CATIE study suggest that the difference in incidence of EPS with an atypical antipsychotic may not be as great when compared with a moderate-potency typical antipsychotic.

The difference in the incidence of EPS between an atypical antipsychotic and a typical antipsychotic has generally involved the comparison of a high-potency typical, specifically haloperidol. Data from the CATIE studies showed that there was no clinically significant difference in the incidence of parkinsonian symptoms and akathisia between the atypical agents and a moderate-potency typical agent, perphenazine. Although a statistically significantly greater number of perphenazine-treated subjects than of atypical-treated subjects discontinued treatment because of EPS (8% vs. 2%–4%), the incidence was low and of limited clinical significance.

In the past, if a patient receiving a typical antipsychotic developed severe parkinsonism or akathisia and did not respond to antiparkinsonian treatment, the recommended strategy was to switch to an atypical antipsychotic. Now, the recommendation can be made to consider the use of a less potent typical antipsychotic as one of the options for treatment, along with possibly changing to an atypical.

For patients with severe refractory EPS who have not responded to standard treatments, the use of clozapine specifically to treat the EPS is indicated (Casey 1989). This is particularly true for akathisia, given its significant negative correlation with the outcome of schizophrenia. This is also true for

patients who do not have any psychotic symptoms, if the EPS are judged to be severe enough to be disabling or potentially life-threatening, such as laryngeal dystonia.

Tardive Dyskinesia and Tardive Dystonia

Historically, TD has been refractory to treatment, which explains the large number of drugs employed in attempts to alleviate the condition. Treatments investigated have included, but are not limited to, noradrenergic antagonists (propranolol and clonidine), antagonists of dopamine and other catecholamines, dopamine agonists, catecholamine-depleting drugs (reserpine and tetrabenazine), GABAergic drugs, cholinergic drugs (deanol, choline, and lecithin), catecholaminergic drugs (Kane et al. 1992), calcium channel blockers (Cates et al. 1993), and selective monoamine oxidase inhibitors (selegiline) (Goff et al. 1993). Based on the investigations of the above drugs, the American Psychiatric Association Task Force on TD concluded that there is no consistently effective treatment for TD (Kane et al. 1992).

There are inherent difficulties in evaluating the effects of any treatment for TD. These include the variability of clinical raters (Bergen et al. 1984), placebo response (Sommer et al. 1994), and the diurnal and longitudinal variability of TD (Hyde et al. 1995; Stanilla et al. 1996). The degree of improvement needs to be greater than the sum of the above variations in order to demonstrate an actual benefit.

The first step in evaluating TD is to determine the type of antipsychotic agent that is being used. If a typical antipsychotic is necessary, it is important to use the lowest dose possible (G. M. Simpson 2000). Second, if anticholinergic antiparkinsonian medications are being used, the patient should be gradually weaned from these medications and the medications then discontinued. Anticholinergic medications will make, in contrast to their effect on other extrapyramidal movements, TD movements worse (see Greil et al. 1984; Jeste and Wyatt 1982).

Some drugs have been shown to have some benefit in the treatment of TD, but they have limitations. Clonazepam has been reported to reduce the movements of TD for up to 9 months, although tolerance to the benefits developed (Thaker et al. 1990). Additional limitations are the inherent problems associated with chronic use of a benzodiazepine. Botulinum toxin is beneficial for treating localized tardive dystonias, particularly laryngeal and cervical dystonias (Hughes 1994). The injections need to be repeated every 3–6 months, and botulinum toxin is not a general treatment for TD. Vitamin E has not consistently been shown to be beneficial in all studies, and a large long-term double-blind study found no benefit for vitamin E compared with placebo (Adler et al. 1999).

Tardive dystonia also tends to be resistant to treatment; however, unlike TD, it may respond to anticholinergic medications (Wojcik et al. 1991) and to reserpine (Kang et al. 1988).

Atypical Antipsychotics for Treatment of Tardive Dyskinesia

Clozapine has been shown to decrease the symptoms of TD (G. M. Simpson and Varga 1974; G. M. Simpson et al. 1978), with the greatest improvement occurring in cases of severe TD and tardive dystonia (Lieberman et al. 1991). These findings have been replicated and suggest that clozapine is unlikely to cause TD (Chengappa et al. 1994; Kane et al. 1993). The disadvantages to clozapine are the potential side effects of agranulocytosis and seizures and the need for regular blood monitoring.

Three possible mechanisms for clozapine's benefit have been proposed. First, clozapine may suppress TD movements in a fashion similar to that of typical antipsychotics. Second, TD may improve spontaneously, given that the typical antipsychotics are no longer present to cause or sustain TD. Such improvement occurs in some patients when antipsychotics are withdrawn. Third, clozapine may have an active therapeutic effect on TD (Lieberman et al. 1991), but the issue remains to be clarified. In some patients, TD movements have recurred on withdrawal of clozapine.

More data demonstrating the potential benefit of the other novel antipsychotics in the prevention and treatment of TD are being reported. A prospective study examined the incidence of emergent dyskinesia in middle-aged to elderly patients (mean age 66 years) being treated with haloperidol and low-dose risperidone (mean total daily dose of 1 mg). The patients treated with risperidone were significantly less likely to develop TD (Jeste et al. 1999). A double-blind prospective study comparing 397 stable patients with schizophrenia who were switched to either risperidone or haloperidol and followed for at least a year found that only 1 of the patients receiving risperidone developed dyskinetic movements, compared with 5 of the patients receiving haloperidol (Csernansky et al. 2002).

In a prospective double-blind study of patients with schizophrenia being treated with either olanzapine or haloperidol and followed for up to 2.6 years, there was a significantly decreased risk for the development of TD with olanzapine. The 1-year risk was 0.52% for olanzapine and 7.45% for haloperidol (Beasley et al. 1999).

The data regarding the effect of quetiapine, ziprasidone, aripiprazole, and paliperidone on TD are more limited; however, any drug that is less likely to produce EPS is probably less likely to produce TD.

The best treatment for TD is prevention. Of the 1,460 subjects involved in the CATIE study, D. D. Miller et al. (2005) found 212 to have probable TD by Schooler-Kane criteria. They found that subjects with TD were older, had a longer duration of receiving antipsychotic medications, and were more likely to have been receiving a conventional antipsychotic and an anticholinergic agent. They also found that substance abuse significantly predicted TD, as well as subjects with higher ratings of psychopathology, parkinsonian symptoms, and akathisia (D. D. Miller et al. 2005).

Patients with TD who are taking typical antipsychotics are candidates for switching to an atypical antipsychotic. In the case of severe TD or dystonia that has been unresponsive to other treatment, the use of clozapine is indicated (G. M. Simpson 2000).

Prophylaxis of Extrapyramidal Side Effects

Prophylactic use of antiparkinsonian agents to prevent EPS is a common, but not completely accepted, practice. Most controlled prospective studies regarding prophylactic use of antiparkinsonian medication have shown that prophylaxis can be beneficial for certain patients who are at high risk but that it is *not* beneficial in routine use across all patient groups (Hanlon et al. 1966; Sramek et al. 1986). Studies that have demonstrated a greater general benefit across all groups have involved the use of very high doses of antipsychotics. Several retrospective studies have also demonstrated that there is a limited need for prophylaxis of EPS (Swett et al. 1977). The retrospective studies that demonstrated a greater benefit from prophylaxis also involved the use of high antipsychotic dosages (Keepers et al. 1983; Stern and Anderson 1979). The prophylactic use of antiparkinsonian medication is not routinely indicated for all patients but should be reserved for those patients at high risk of developing ADRs.

The risk factors for developing ADRs include younger age (<35 years), higher doses of antipsychotic, higher potency of antipsychotic, intramuscular route of delivery, (possibly) male gender (Sramek et al. 1986), and history of ADRs from a similar antipsychotic (Keepers and Casey 1991). The use of cocaine has been suggested as a possible risk factor (van Harten et al. 1998; see Table 34–4 for summary).

Dosages that have been used for prophylaxis are 1–4 mg/day for benztropine, 5–15 mg/day for trihexyphenidyl, and 75–150 mg/day for diphenhydramine, although the dose required to achieve prophylaxis is highly variable for each individual and can only be determined by trial and error (Moleman et al. 1982; Sramek et al. 1986). Serious anticholinergic side effects, such as acute urinary retention or paralytic ileus, can occur even in a young patient; therefore, high doses of anticholinergics cannot be used with impunity, even for short periods.

Prophylactic anticholinergics for ADRs need only be used for a limited time because 85%–90% of ADRs occur within the first 4 days of treatment, and the incidence drops to nearly zero after 10 days (Keepers et al. 1983; Singh et al. 1990; Sramek et al. 1986). After 10 days, anticholinergics can be weaned slowly while the patient is being observed for development of parkinsonism or akathisia.

Depot Antipsychotics

In patients receiving depot antipsychotics, prophylactic anticholinergics also only need to be used for patients at high risk of developing ADRs (Idzorek 1976). However, the onset and characterization of EPS may be different in people receiving depot antipsychotics, including more bizarre dystonic reactions (G. M. Simpson 1970). The buildup of antipsychotic levels with depot antipsychotics can lead to the development of EPS at later stages of treatment; therefore, an ongoing evaluation is necessary. Some patients receiving fluphenazine decanoate were found to experience EPS only between days 3 and 10 following injection (McClelland et al. 1974).

Duration of Treatment

Withdrawal Studies

Studies investigating the withdrawal of antiparkinsonian agents have demonstrated that not all subjects redevelop EPS, a serendipitous finding noted when only 20% of patients withdrawn from benztropine in preparation for a trial of a new antiparkinsonian agent developed recurrent parkinsonian symptoms. This led to the suggestion that antiparkinsonian agents should be withdrawn after 2 months and that their use should only be resumed in patients who develop EPS again (Cahan and Parrish 1960).

Subsequently, other withdrawal studies have been conducted that revealed wide-ranging rates of EPS recurrence. Differences in rates of recurrence are related to the varying methodologies involved in the studies, including methods of rating and the initial reason for treatment with anticholinergics —prophylaxis or active treatment (Ananth et al. 1970). The types, dosages, and combinations of antipsychotics used—the same factors that contribute to the initial development of EPS—have also been major factors in determining reoccurrence rates (Baker et al. 1983; McClelland et al. 1974). In addition, there are inherent difficulties in evaluating EPS, including the role of psychological factors and placebo effect (Ekdawi and Fowke 1966; G. M. Simpson et al. 1972; St. Jean et al. 1964).

Almost all anticholinergic withdrawal studies have involved abrupt withdrawal of the anticholinergic medications. Abrupt, compared with gradual, withdrawal is more likely to result in a return of EPS. Gradual withdrawal studies have demonstrated that a large percentage (up to 90%) of patients can be completely withdrawn from anticholinergic medications without developing EPS, while the remaining patients can have their EPS controlled with a considerably reduced dose (Double et al. 1993; Ungvari et al. 1999).

Withdrawal Syndrome

Almost all anticholinergic withdrawal studies have involved abrupt withdrawal of the anticholinergic medications. Specific studies to evaluate the effect of cholinergic sensitization by anticholinergic agents on the subsequent development of EPS following withdrawal of the anticholinergic agent have not been done. There is evidence that sensitization can take place and contribute to EPS and other symptoms. Some patients with no symptoms of EPS prior to treatment with anticholinergics did develop EPS on withdrawal of the anticholinergics (Klett and Caffey 1972; G. M. Simpson et al. 1965). Withdrawal symptoms of nausea, vomiting, diaphoresis, sebaceous secretion, and restlessness can occur following withdrawal of any psychotropic with anticholinergic properties (Luchins et al. 1980). These symptoms are most likely the result of cholinergic rebound and perhaps sensitization following removal of the cholinergic blockade of the drug (G. M. Simpson et al. 1965). Abrupt clozapine withdrawal can produce agitation, delirium, and severe choreoathetoid movements, which are also probably the result of cholinergic rebound related to the very high antimuscarinic activity of clozapine (Stanilla et al. 1997).

The potential for cholinergic sensitization with the use of anticholinergic agents is significant because EPS following withdrawal may initially be more severe but may diminish over time without treatment. Potential cholinergic sensitization leading to subsequent EPS is also a reason for limiting the routine use of prophylactic anticholinergic agents.

The conclusion that can be drawn from the withdrawal studies is that patients are more likely to develop EPS on withdrawal of antiparkinsonian agents if the risk factors for developing EPS are present. If these risk factors are minimized, the rate of EPS recurrence is lowered.

In patients who experience a reoccurrence of EPS, the EPS generally reappear within 2 weeks and control is easily reestablished (Klett and Caffey 1972). Patients respond rapidly and often require smaller doses of antiparkinsonian medications for control while continuing to take the same dose of antipsychotic (McClelland et al. 1974).

It needs to be emphasized that the withdrawal of antiparkinsonian agents should be conducted slowly and gradually over weeks or months, not abruptly, as was done in the reported studies. Patients should be evaluated for recurrence of EPS following a partial dose reduction of the antiparkinsonian agent. This process should be continued until the antiparkinsonian agent is completely withdrawn or until the lowest dose for maintenance control is achieved.

CONCLUSION

The unique properties of chlorpromazine and other similarly active agents in ameliorating psychotic symptoms and producing parkinsonian side effects were described in the early 1950s by French psychiatrists. Theories soon arose regarding the relationship between these two properties. The recognition of the benefits of reducing Parkinson-like side effects led to investigations of methods to reduce EPS and to the development of instruments to measure EPS. The debate regarding the routine and prophylactic use of antiparkinsonian agents has continued since that time. It appears that prophylactic antiparkinsonian agents need to be used in some situations, but probably less frequently and for briefer periods of time than has generally been the practice. The trend toward the use of lower dosages of antipsychotics should also lead to a decreased need for the use of antiparkinsonian agents.

Finally, the advent of atypical antipsychotic agents has opened a new chapter in both the treatment and prevention of EPS and suggests that, in the future, EPS will be less of a problem than they have been in the past.

A summary of an American Psychiatric Association Task Force report on TD suggested that "[a] deliberate and sustained effort must be made to maintain patients on the lowest effective amount of drug and to keep the treatment regimen as simple as possible" (Baldessarini et al. 1980, p. 1168) and to discontinue anticholinergic drugs as soon as possible. Apart from a greater emphasis on avoiding the initial use of antiparkinsonian agents, this statement remains valid.

Chapter 35. Lithium

HISTORY AND DISCOVERY

First used in the 1800s as a medicinal treatment, lithium was touted for a wide range of medical woes—including gout and neurological and gastrointestinal ailments—and was used as a table salt substitute and even sold in bottled beverages (El-Mallakh and Jefferson 1999). After noting its sedating properties in animals, Cade (1949) first described the successful treatment of mania with lithium salts. The U.S. Food and Drug Administration (FDA) approved lithium for use in treating acute mania in 1970 and for the prophylaxis of bipolar disorder 4 years later (Jefferson and Greist 1977). However, lithium did not come onto the market easily in the United States. Pharmaceutical companies were reluctant to produce this inexpensive drug that they could not patent (Kline 1973).

Lithium has stood the test of time. Despite a growing number of choices for the treatment of bipolar disorder, lithium remains a cost-effective and efficacious treatment. Baldessarini and Tondo (2000) questioned whether lithium has remained stable in efficacy across the decades. Analyzing 11 controlled and 13 open studies of lithium treatment, as well as their own data, they concluded that lithium's efficacy has remained constant but that some clinical research settings may serve a more complex and refractory patient population than the population typically seen in psychiatric practice.

Wyatt et al. (2001) computed the savings from lithium use during the years 1970 and 1991, estimating that more than $8 million was saved annually, after consideration of treatment costs, lost earnings, and lost productivity. Lithium is still a highly cost-effective treatment for bipolar disorder (Chisholm et al. 2005). In contrast to most other medications for bipolar disorder, lithium is available generically and is relatively inexpensive. The pharmaceutical industry spends considerable funds for research and marketing for drugs still on patent, and therefore lithium has achieved an orphan status, with little incentive for private funding of studies with lithium (Rosenthal 2001).

> Lithium is effective and well tolerated, especially at moderate serum lithium concentrations. . . . One factor that may be responsible for lithium's fall from grace among clinicians and patients is its status as an "orphan" or "poor relative." Since lithium is cheap and unpatented, no wealthy drug company has any interest in demonstrating its merits as a mood stabilizer. There are no lavishly catered all-star symposia at major psychiatric meetings to sing the praises of this humble salt. And when did you last see a pen, notepad, calendar, or trinket with "Lithium" embossed on it? Finally, lithium is regarded as old news and, as such, is less appealing to psychiatric researchers eager to make their mark on the field. (Rosenthal 2001, p. 973)

STRUCTURE–ACTIVITY RELATIONS

Lithium is the lightest alkali metal and a monovalent cation, and it shares some properties with sodium, potassium, and calcium (Baldessarini 1996; Ward et al. 1994). It is the third element of the periodic table. Substitution or competition with other cations may contribute to its effects (Ward et al. 1994).

PHARMACOLOGICAL PROFILE

Lithium is minimally protein bound, does not undergo biotransformation, and is renally eliminated (Kilts 2000). The narrow therapeutic index necessitates careful drug monitoring. Lithium appears to

affect multiple neurotransmitter systems and affects second-messenger systems such as cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) (Ward et al. 1994).

PHARMACOKINETICS AND DISPOSITION

Lithium is available in multiple preparations, including lithium carbonate tablets and capsules, lithium citrate, and slow-release forms (Jefferson et al. 1983). Lithium is absorbed from the gastrointestinal tract and renally excreted unchanged in approximately 24 hours (Baldessarini and Tarazi 2001). Peak plasma concentrations are reached within 1–2 hours with rapid-release preparations and 4–5 hours after sustained-release formulations (Finley et al. 1995). Brain levels, as measured by in vivo nuclear magnetic resonance, are highest 0–2 hours after peak serum concentrations are achieved (Komoroski et al. 1993). Lithium is not protein bound and is evenly distributed in total body water space (Jermain et al. 1991). Lithium excretion is controlled by osmotic factors and is a function of renal sufficiency (Birch et al. 1980). Steady-state concentrations are achieved within 4–5 days (Keck and McElroy 2002).

MECHANISM OF ACTION

Despite extensive research, the exact mechanism of action of lithium as a mood stabilizer has yet to be elucidated. The importance of defining lithium's mechanism of action is twofold: 1) to shed light on the disorder's etiology and 2) to open up investigation into new treatments for bipolar disorder (Phiel and Klein 2001). Multiple theories, based on animal models and limited studies in humans, have been proposed; those with the most compelling evidence are reviewed here.

Eventually, an integrated theory of lithium's action will be necessary because it has numerous physiological effects. Ikonomov and Manji (1999) have offered the "initiation and adaptation paradigm" as a nicely integrated view of lithium's actions: lithium has both immediate short-term effects and effects that emerge only after long-term treatment. They propose that the immediate effects eventually cause downstream changes in gene expression.

Inositol Depletion

There has been much focus on the role of the inositol cycle in the clinical effects of lithium. Lithium is a noncompetitive inhibitor of inositol monophosphatase, depleting free inositol within 5 days of treatment initiation (Berridge et al. 1989). These changes last for 3–4 weeks after lithium's discontinuation (Moore et al. 1997). Depletion of free inositol can lead to effects on neurotransmitter and second-messenger systems linked to the inositol cycle. For example, adrenergic, serotonergic, and cholinergic receptor subtypes are coupled to the cycle via G proteins, and the cycle in turn regulates protein kinase C action, which appears to be influenced by lithium treatment in mania (Hahn et al. 2005). Lithium decreases levels of protein kinase C isoenzymes in the frontal cortex and hippocampus, two areas of the brain known to be involved in the pathophysiology of mood disorders (Drevets et al. 1997; Ketter et al. 1997; Manji et al. 1993, 1999; Rajkowska et al. 1999).

Berridge et al. (1989) suggested that lithium, because it is a noncompetitive inhibitor of inositol monophosphatase, only affects *activated* systems via the inositol-depletion mechanism; basal functioning of the cycle is not affected. This would account for lithium's profound effects on mood in bipolar and depressive disorders and its relatively minor effects on mood in control subjects (Judd 1979).

Lithium affects rearing behavior in rats, which is reversible by inositol administration. Also, administration of inositol inhibits the epileptogenic effects of pilocarpine challenge after lithium administration in rats (Belmaker et al. 1996). Of note, depression is associated with low cerebrospinal fluid inositol levels in humans (Barkai et al. 1978). Exogenous inositol can alleviate depression (Levine et al. 1993, 1995) and panic attacks (Benjamin et al. 1995). Belmaker et al. (1996) suggested a complex "pendulum" relationship between inositol and lithium, which may be a basis for

understanding lithium's antimanic and antidepressant effects.

In rats and humans, inositol attenuates some of the side effects of lithium, particularly polyuria (Bersudsky et al. 1993; Geisler et al. 1972) resulting from either lithium's effects on the inositol cycle or inositol's osmotic effects (P.A. Garcia and Burg 1991). Death due to lithium toxicity in rats is not prevented by inositol administration, suggesting a different mechanism (Belmaker et al. 1996).

Glycogen Synthase Kinase Inhibition

Lithium inhibits glycogen synthase kinase–3 (GSK-3) (Klein and Melton 1996; Li et al. 2007). Valproic acid also inhibits GSK-3, making this theory attractive because it involves a common mechanism in two known mood stabilizers (G. Chen et al. 1999). GSK-3 is an inhibitor of the Wnt protein signaling pathway, which affects neuronal signal transduction. Lithium thus would be predicted to mimic Wnt signaling (Phiel and Klein 2001). Wnt signaling stimulates a cascade of events that leads to stimulation of protein kinase C activity (Grahame-Smith 1998; Williams and Harwood 2000). Thus, lithium's actions on both the inositol cycle and the GSK 3 signaling pathway lead to a common effect on protein kinase C.

Wnt signaling, which is inhibited by and in turn inhibits GSK-3 activity, also causes axonal remodeling in mouse cerebellar cells (Hall et al. 2000). GSK-3 activity elevation can cause breakdown of catenins, which can cause structural changes in cytoskeleton (Cotter et al. 1998). β-Catenin produces changes in gene expression that are related to cytoskeletal structures. Lithium stabilizes cytoskeleton structures (Williams and Harwood 2000).

Lithium's Effects on Neurotransmitter Systems

Perhaps because of its effects on second-messenger systems, lithium brings about changes in all of the major neurotransmitter systems in the brain. Chronic administration of lithium in mice increases and stabilizes glutamate uptake. This could, in part, explain lithium's antimanic effect because it results in overall reduction of an excitatory neurotransmitter (Dixon and Hokin 1998). Lithium also normalizes low cerebrospinal fluid γ-aminobutyric acid levels in bipolar subjects (see Berrettini et al. 1983, 1986).

Lithium enhances norepinephrine and serotonin function in the central nervous system, which could explain its antidepressant effects (Price et al. 1990; Schildkraut et al. 1969; D. N. Stern et al. 1969). Of particular interest is lithium's confirmed antagonistic action at serotonin$_{1A}$ (5-HT$_{1A}$) and serotonin$_{1B}$ (5-HT$_{1B}$) autoreceptors (Haddjeri et al. 2000; Massot et al. 1999); such action would increase serotonin availability in the synaptic cleft (Shaldubina et al. 2001). Clinically, 5-HT$_{1A}$ may be involved in alleviation of depression, and 5-HT$_{1B}$ receptors may play a role in the regulation of sleep, sensorimotor inhibition, and locomotor activity (Monti et al. 1995; Sipes and Geyer 1996).

Lithium, Mood Disorders, and Circadian Rhythms

Bipolar disorder and depression are associated with disturbances in the body's natural rhythms; the most clinically evident of these is the disruption of the sleep–wake cycle, but the temperature cycle, cortisol cycle, and others are also affected (Hallonquist et al. 1986; Healy and Waterhouse 1995). Associated with such changes is a decoupling of the major and minor oscillators located in the hypothalamus, which in healthy subjects work in a synchronized fashion. Lithium administration causes the oscillators to resynchronize (DeMet and Chicz-Demet 1987; Klemfuss 1992). The mechanism by which resynchronization occurs is unknown; it is likely *not* via the inositol depletion mechanism (Lakin-Thomas 1992, 1993). Also, a cause–effect relation has not been established for circadian rhythm abnormalities and mood disorders; the changes seen in circadian rhythms could be a cause of bipolar disorder and/or unipolar depression or could be an effect of the disease process.

INDICATIONS AND EFFICACY

Bipolar Disorder

Acute Mania

Cade (1949) first published data on the efficacy of lithium in mania more than half a century ago. As we begin the twenty-first century, lithium remains one of the most efficacious treatments for bipolar disorder.

Lithium versus placebo

Lithium has been shown to be more efficacious than placebo in acute mania in randomized trials (Bowden et al. 1994, 2005; Goodwin et al. 1969; Maggs 1963; Schou et al. 1954; Stokes et al. 1971). Analysis of response rates in these studies indicates that lithium was at least somewhat efficacious in the treatment of mania in 87 of 124 patients (70%) (Keck et al. 2000).

Lithium versus typical antipsychotics

In studies that used various designs, lithium was more effective than chlorpromazine and other traditional antipsychotic medications in the treatment of acute mania. In a review of studies, Goodwin and Zis (1979) found lithium efficacious in at least 70% of patients, as defined by remission or marked improvement. Lithium also worked more quickly than typical antipsychotics and was better tolerated (Takahashi et al. 1975). In addition, patients with psychotic symptoms during a manic episode tend to have a better response to lithium prophylactic treatment than do those without psychosis (see Rosenthal et al. 1979).

In a 3-week double-blind study of lithium, haloperidol, and their combination for acute mania, patients who received haloperidol or haloperidol plus lithium had more significant improvement than did those who received lithium alone (Garfinkel et al. 1980). The combination of lithium and haloperidol was as well tolerated as haloperidol alone. In patients with schizoaffective disorder, lithium was as effective as chlorpromazine in acute mania (Brockington et al. 1978). More recently, Segal et al. (1998) reported that inpatients with acute mania responded equally well to lithium, haloperidol, and risperidone. Lithium has been used as a comparator in trials versus atypical (second-generation) antipsychotic medications, but these studies primarily assess the efficacy of the antipsychotic in a noninferiority approach rather than demonstrate significant differences between lithium and the atypicals. To date, there is no obvious effect-size difference between any agent and lithium for antimanic effects. By and large, antipsychotics appear to work faster. Most probably, genetic variables mediate the likelihood and magnitude of treatment response to different agents in different patients, so although we can detect no overall efficacy differences, for individual patients there are likely great differences.

Lithium versus calcium channel blockers

Lithium appears superior to verapamil in the treatment of mania (Walton et al. 1996).

Lithium versus electroconvulsive therapy

Small et al. (1988) compared the effects of lithium with those of electroconvulsive therapy (ECT) for acute mania. Patients who received ECT had significantly more improvement during the first 2 months of treatment than did those who received lithium carbonate, especially those with mixed mania. After 8 weeks, no significant differences were found between the groups.

In a retrospective chart review, Black et al. (1987) found that a significantly greater percentage of patients who received ECT (78%) had "marked improvement" than those who received lithium, either "adequately or inadequately" (62%, 56%). Almost 70% of the patients who did not respond to lithium experienced "marked improvement" after treatment with ECT.

Lithium versus anticonvulsants

Double-blind, randomized studies have suggested that carbamazepine and lithium are equally effective for acute mania (Lerer et al. 1987; Small et al. 1991). However, neither trial included a placebo arm. Swann et al. (1999) reported that for patients who had experienced a greater number of previous episodes, divalproex was more effective than lithium for acute mania, as determined by a 3-week double-blind study. For patients with a history of fewer episodes, lithium had no significantly different effect compared with divalproex in acute mania. Bowden et al. (1994) reported that both lithium and divalproex sodium were significantly more effective than placebo in the treatment of acute mania. Almost one-third of the patients receiving either lithium or divalproex dropped out of the study secondary to lack of efficacy, compared with approximately half of the patients who received placebo.

In a meta-analysis of the efficacy of lithium, valproate, and carbamazepine in mania, no significant differences in efficacy were found among the three groups (Emilien et al. 1996). Only some of the included studies were placebo controlled. Anticonvulsants were generally better tolerated than lithium. Neurological abnormalities may predict a better response to anticonvulsants than to lithium in mania. Patients with electroencephalogram abnormalities are more likely to respond to valproate than to lithium (Reeves et al. 2001). One double-blind study suggested that lamotrigine may be as effective as lithium for acute mania (Ichim et al. 2000).

Mixed mania, the co-occurrence of mania with depression, may predict a poor response to lithium. In a double-blind study of acute mania, depressive symptoms were associated with a poorer response to lithium (Swann et al. 1997). Other predictors of a poor antimanic response to lithium include rapid cycling and substance abuse (Dunner and Fieve 1974; Goodwin and Jamison 1990; Himmelhoch et al. 1976).

Rapid efficacy is desirable in a mood stabilizer, and rapid administration of lithium has been preliminarily studied. Lynn et al. (1971) discussed lithium "loading" for acute mania. More recently, Keck et al. (2001) assessed the safety and efficacy of rapid lithium administration in the treatment of acute mania; in an open-label study of 15 inpatients, 20 mg/kg/day appeared well tolerated and efficacious for acute mania.

Bipolar Depression

Lithium is a first-line treatment for acute bipolar depression (Compton and Nemeroff 2000). In 2004, an expert consensus report found lithium monotherapy to be both a preferred initial medication for mild to moderate depression in bipolar I disorder and a component of an initial medication regimen in severe nonpsychotic and psychotic depression in bipolar I disorder (Keck et al. 2004). The American Psychiatric Association's (2002) "Practice Guideline for the Treatment of Patients With Bipolar Disorder" states that the first-line treatment for bipolar depression is pharmacotherapy with either lithium or lamotrigine, with the former approach as the better-supported option.

Placebo-controlled studies of lithium in bipolar depression generally have reported efficacy. Goodwin and Jamison (1990) analyzed the placebo-controlled trials that have been completed in bipolar depression and found that 79% of the bipolar patients in those trials had either a complete or a partial response to lithium. Placebo-controlled trials that show the efficacy of lithium in bipolar depression include those by Baron et al. (1975), Donnelly et al. (1978), Fieve et al. (1968), Goodwin et al. (1969, 1972), Greenspan et al. (1970), Mendels (1975), and Noyes et al. (1974). These studies generally were small (involving between 3 and 40 patients [Goodwin et al. 1972]). One study, by Stokes et al. (1971), did not show a significant benefit of lithium over placebo, but lithium was administered for only a 10-day period in that trial.

Suicide: Is Lithium Protective?

Twenty-five percent to 50% of bipolar patients attempt suicide during their lifetime (Compton and

Nemeroff 2000). On average, studies of deaths among individuals with bipolar disorder indicate that 19% complete suicide (see Goodwin and Jamison 1990). In an analysis of studies of lithium treatment (Schou 1998), patients treated with lithium had a lower overall mortality rate than bipolar patients in general. Schou (1998) studied a population of approximately 2,000 patients who received lithium and found that these patients did not have a significantly higher suicide rate than the general population. After discontinuation of the lithium, the mortality rate increased. Fewer patients attempted or committed suicide while treated prophylactically with lithium than when they were not.

Also, Tondo et al. (1997) reviewed studies of the use of lithium in the treatment of major mood disorders; these included 28 studies that involved more than 17,000 patients. Risks of completed and attempted suicides were 8.6-fold higher in patients who were not given lithium compared with those who were. They also found increased rates of suicide after lithium discontinuation (Baldessarini et al. 1999). The risk of suicide with lithium discontinuation may be decreased with gradual discontinuation. Lithium may have a specific antisuicidal effect in addition to mood-stabilizing properties (Aherns and Muller-Oerlinghausen 2001). In addition to a marked reduction in suicide attempts in lithium responders, lithium seems to reduce suicide attempts independent of classification of clinical response (i.e., excellent, moderate, poor).

In meta-analyses of studies of lithium treatment in major mood disorders, Tondo et al. (2001) and Baldessarini et al. (2006) found significantly lower suicide risk for subjects who were receiving treatment with lithium. However, Coryell et al. (2001) conducted a case–control study in which patients with major mood disorders who completed or attempted suicide were matched with control subjects who were receiving similar treatment (antidepressant and/or mood-stabilizing medication). The patients who committed suicide were slightly less likely to be using lithium, but the difference was not statistically significant.

Methodological problems exist in the studies that have examined lithium and suicide risk, and large-scale prospective studies are necessary for definitive recommendations to inform treatment decisions (Gelenberg 2001).

Prophylaxis and Maintenance

Once the diagnosis of bipolar disorder is established, a patient will be afflicted for the rest of his or her lifetime, with ongoing risks of relapse and recurrence. Therefore, prophylactic or maintenance therapy is often considered after the resolution of an acute mood episode. Lithium is the best-studied drug for this indication.

Tondo et al. (2001) found lithium effective in long-term use (more than 1 year) in decreasing frequency of mood episodes and "time ill" in patients with bipolar I and bipolar II disorders. Benefits of lithium treatment were not significantly different among patients with psychosis or mixed episodes, rapid cycling, or more classic forms. There was no decrease in efficacy with long-term use. Early commencement of lithium therapy and a diagnosis of bipolar II disorder may predict a better course of illness (Tondo et al. 1998).

Rosenthal et al. (1979) also found that psychotic symptoms during manic episodes predicted a good response to lithium prophylaxis in bipolar I patients. The chronological pattern of illness also may predict response to lithium prophylaxis: the pattern mania–depression–euthymia is associated with better response than depression–mania or rapid-cycling bipolar disorder (Maj 1990). Additionally, a poorer response after 1 year of lithium therapy is associated with poor response to lithium within the first 6 months, more severe episodes, higher ratio of manic episodes to depressive episodes, and being unmarried (Yazici et al. 1999).

Kulhara et al. (1999) found that only 24% of the patients with bipolar disorder followed up in a lithium clinic were free of mood episodes while receiving lithium prophylaxis (duration of monitoring: average

= 11 years, range = 2–27 years). Noncompliance and/or subtherapeutic lithium blood levels (<0.4 mEq/L), high number of psychosocial stressors, higher number of depressive episodes before lithium treatment, and poor social supports may predict poorer response to lithium prophylaxis (Kulhara et al. 1999). Patients had significantly fewer mood episodes after starting lithium.

Starting lithium early in the course of illness predicts a better response to treatment (Franchini et al. 1999). Time of onset of lithium prophylaxis was significantly related to outcome of lithium treatment (P <0.001), after polarity, sex, age at onset, duration of illness, and duration of lithium prophylaxis were accounted for.

Psychotic symptoms during a manic episode also have been associated with better response to lithium prophylaxis (Rosenthal et al. 1979).

Lithium appears superior to carbamazepine in the prophylactic treatment of classic bipolar I disorder. Denicoff et al. (1997) compared the efficacy of lithium, carbamazepine, and their combination in the prophylactic treatment of bipolar disorder. Patients were randomly assigned to double-blind treatment for 1 year with lithium or carbamazepine, experienced a crossover to the other drug in the second year, and received a combination of the two in the third year. Thirty-one percent failed to complete a full year of lithium therapy because of lack of efficacy, 37% failed to complete a full year of carbamazepine therapy because of lack of efficacy, and 24% failed to complete a full year of combination therapy because of lack of efficacy. Lithium was more effective than carbamazepine for prophylaxis of mania; patients with rapid cycling did poorly with either monotherapy (28% responded to lithium, compared with 19% to carbamazepine), and patients with rapid cycling did significantly better on the combination of the two drugs than on either alone.

In a randomized study, Kleindienst and Greil (2000) found that lithium was superior to carbamazepine in treating classic mania, but carbamazepine was more efficacious for nonclassic features, such as mixed episodes and comorbidity.

In a comparison of lithium, divalproex, and placebo in a 1-year treatment study of patients with bipolar I disorder after recovery from an index manic episode, Bowden et al. (2000) found that median times to 50% survival without mood episode were 40 weeks for divalproex, 24 weeks for lithium, and 28 weeks for placebo, although the differences were not statistically significant. Patients who received divalproex remained in treatment significantly longer than did those who received lithium. Calabrese et al. (2005) found similarly high rates of relapse in patients with rapid-cycling bipolar disorder randomly assigned to either lithium or valproate monotherapy (56% and 50% relapse rates, respectively). In patients with mixed or manic episodes who responded to cotreatment with lithium and olanzapine, investigators conducted a double-blind, randomized maintenance trial of lithium versus olanzapine (Tohen et al. 2005). Recurrence rates were similar between groups, with 38.8% of those on lithium and 30.0% on olanzapine experiencing relapse, with similar prophylaxis for depressive episodes among treatments and some advantage for prevention of mania and mixed episodes with olanzapine.

The combination of lithium and valproate also has been studied as maintenance therapy for bipolar disorder: the two may work synergistically (Solomon et al. 1998).

Quitkin et al. (1981) assessed the efficacy of lithium with and without the antidepressant imipramine in the prophylaxis of bipolar I disorder. Few depressive episodes occurred in either group, and the risk of mania increased with the addition of imipramine. Most relapses occurred in the first 6 months of treatment.

Maintenance dosing

To be effective in prophylaxis, lithium must be administered daily. Lithium administration every other day is not as effective as daily dosing (Jensen et al. 1995). Perry et al. (1984) formulated tables to

assist in the determination of maintenance dosage requirements, based on 24-hour serum lithium levels after the administration of a 1,200-mg test dose. Once-daily dosing at bedtime yields higher brain-to-serum ratios of lithium levels than twice-daily dosing schedules (Soares et al. 2001). Investigators have observed substantial variation in brain lithium levels among individuals with similar serum lithium levels (Gonzalez et al. 1993).

Unipolar Depression

Analysis of five controlled trials of lithium augmentation for unipolar depression found significant improvement in 56%–96% of patients (Austin et al. 1991; Heit and Nemeroff 1998; Heninger et al. 1983; Kantor et al. 1986; Schopf et al. 1989; Stein and Bernadt 1993; Zusky et al. 1988). In treatment-refractory depression, open-label data support the addition of lithium to antidepressants, including tricyclics, trazodone, and selective serotonin reuptake inhibitors (SSRIs) (De Montigny et al. 1981, 1983, 1985; Dinan 1993; Fontaine et al. 1991; Price et al. 1986). Double-blind studies support the use of lithium for augmentation of tricyclics, monoamine oxidase inhibitors (MAOIs), trazodone, and SSRIs (Baumann et al. 1996; Fava et al. 1994; Heninger et al. 1983; Joffe et al. 1993; Kantor et al. 1986; Katona et al. 1995; Nierenberg et al. 2006; Schopf et al. 1989; Zusky et al. 1988). In the large Sequenced Treatment Alternatives to Relieve Depression (STAR*D) multisite trial, 15.9% of subjects who did not experience remission with citalopram monotherapy and another medication trial experienced remission after the addition of lithium (Nierenberg et al. 2006).

Time of onset of lithium action as an adjunct to antidepressants remains unclear. Also, new studies are needed to determine the appropriate duration of treatment with lithium augmentation and the appropriate serum lithium levels (Heit and Nemeroff 1998).

Personality Disorders

In a double-blind crossover study, Rifkin et al. (1972) studied lithium and placebo in patients with "emotionally unstable character disorder," consisting of "short mood swings, both depressive and hypomanic, lasting hours to a few days" as well as "chronically maladaptive behavior." Patients were significantly more likely to show improvement while receiving treatment with lithium. LaWall and Wesselius (1982) reported five cases in which patients with borderline personality disorder (DSM-III; American Psychiatric Association 1980) showed clinical improvement with lithium treatment.

Aggression and Impulsivity

In placebo-controlled trials of adults without bipolar disorder, lithium has been effective for aggressive behavior (Worrall et al. 1975). Lithium reduced the frequency of aggressive episodes in patients with mental retardation, per retrospective chart reviews (Luchins and Dojka 1989; Spreat et al. 1989) and prospective double-blind, placebo-controlled clinical trial data (Craft et al. 1987). Both open-label and double-blind, placebo-controlled data have found lithium to be effective in reducing aggression in children with conduct disorder (Campbell et al. 1995; Malone et al. 1994, 2000). There may be broad public health implications for the relation between lithium and aggression. In one study, counties with higher lithium levels in drinking water had lower rates of suicide, homicide, and rape than did counties with lower lithium levels (Schrauzer and Shrestha 1990). Lithium treatment has been demonstrated to decrease impulsive gambling in individuals with bipolar spectrum disorders (Hollander et al. 2005).

Anxiety

Information on the use of lithium in anxiety disorders is limited. Open-label (Van der Kolk 1983) and case-report (Forster et al. 1995; Kitchner and Greenstein 1985) data suggest efficacy in posttraumatic stress disorder. Case reports support a role for lithium in treating refractory panic disorder (Feder 1988) and obsessive-compulsive disorder (Golden et al. 1988; T. A. Stern and Jenike 1983). However, two controlled trials failed to demonstrate efficacy for lithium in the treatment of obsessive-

compulsive disorder (McDougle et al. 1991; Pigott et al. 1991).

USE IN SPECIAL POPULATIONS

Children and Adolescents

Lithium is FDA approved for the treatment of bipolar disorder in adolescents (Ryan et al. 1999). Lithium has a large effect size in the open-label treatment of acute mania or mixed episodes in children and adolescents (Kowatch et al. 2000). Geller et al. (1998a) conducted a randomized trial of lithium for adolescents with bipolar disorder and secondary substance abuse and found that lithium was significantly more efficacious than placebo for both bipolar disorder and substance abuse. Geller et al. (1998b) found no significant differences in treatment outcomes between lithium and placebo in a double-blind trial of prepubertal major depression. In an open study of lithium for bipolar depression in adolescents with bipolar I disorder, investigators found a large effect size and noted response and remission rates of 48% and 30%, respectively (Patel et al. 2006). Findling et al. (2005) conducted a randomized, double-blind maintenance trial of lithium versus divalproex in children 5–17 years of age who were initially stabilized for mania/hypomania on a combination of lithium and divalproex. They observed similar time to relapse with both treatments.

Saliva and serum lithium levels have been correlated in children receiving lithium maintenance treatment, and monitoring of saliva levels may someday play a role in monitoring lithium levels (Spencer et al. 1990). After weight and serum lithium levels were controlled for, younger age is associated with more side effects (Campbell et al. 1991).

The Elderly

S.T. Chen et al. (1999) retrospectively assessed the response of patients at least 55 years old with mania to either lithium or valproate. Overall, significantly more patients improved with lithium, especially in cases of classic mania, whereas the two drugs had similar results when considering only the cases of mixed mania. They also found the therapeutic range for elderly patients to be similar to that for younger adults: ≥0.8 mmol/L.

Despite possibly greater efficacy, lithium may cause more side effects and be more costly in the elderly. Although a year's supply of lithium costs less than divalproex, these savings were offset by higher annual laboratory costs (Conney and Kaston 1999). The lithium group also experienced more adverse events, further increasing medical expenditures. Elderly patients with neurological or other medical conditions may respond less well to and experience more side effects from lithium than from anticonvulsant mood stabilizers (McDonald and Nemeroff 1996). Elderly patients may respond less well to lithium augmentation for refractory unipolar depression, and older age may predict increased incidence of side effects (Flint and Rifat 1994). On the basis of pharmacokinetic differences, Hardy et al. (1987) suggested that elderly patients may require up to one-third or one-half less lithium than younger patients. However, Slater et al. (1984) did not find a correlation between age and required lithium dosage in adults.

Medical comorbidity may be a consideration in elderly patients. Volume depletion, use of nonsteroidal anti-inflammatory drugs, and use of thiazide diuretics can increase lithium levels (Stoudemire et al. 1990). Also, patients with kidney disease receiving hemodialysis do not eliminate lithium other than through dialysis. Lithium should only be given after a dialysis treatment and need not be given daily (Stoudemire et al. 1990).

Lithium appears to have neuroprotective effects, decreasing oxidative damage, and could play a role in the prevention of neurocognitive decline in aging, although the clinical implications of this remain to be determined (Bachmann et al. 2005; Cui et al. 2007; Shao et al. 2005; Tsaltas et al. 2007). Animal models suggest lithium may prevent Alzheimer's disease by inhibition of GSK-3 and its effect on tau protein phosphorylation and role in neurofibrillary tangle formation (Engle et al. 2006; Phiel et al.

2003; Su et al. 2004; Yoshida et al. 2006). In addition to neuroprotective effects, lithium appears to exert neurotrophic factors and aid in neurogenesis as demonstrated in animal models (G. Chen et al. 2000).

Pregnant/Lactating Women

The risks and benefits of lithium treatment must be carefully assessed in the context of pregnancy and breast feeding. Data suggest that lithium exposure during pregnancy is less harmful than experts believed in past decades. In an analysis of published studies of lithium exposure during pregnancy, the association between lithium use and teratogenicity appeared weaker than was assumed in the 1970s (L. S. Cohen et al. 1994). Ebstein's anomaly, a cardiac malformation, was in the past thought to be a relatively high risk of lithium use in the first trimester of pregnancy (Weinstein and Goldfield 1975). In Ebstein's anomaly, a dysplastic tricuspid valve may yield tricuspid regurgitation, and clinical manifestations include cyanosis and atrial tachyarrhythmias. The condition can be surgically treated. In fact, although the overall risk of Ebstein's anomaly may be higher with lithium use than without, because the condition is quite rare in the general population (1 per 20,000 live births), prevalence associated with lithium use is still low. First-trimester exposure to lithium results in 0.05%–0.1% prevalence of Ebstein's anomaly, and relative risk is 10–20 compared with the general population (L. S. Cohen and Rosenbaum 1998). By comparison, this risk is substantially lower than the risk of neural tube defects with some anticonvulsants used for mood stabilization.

Many mood stabilizers are potentially teratogenic (see Llewellyn et al. 1998). For example, up to 5% prevalence of neural tube defects or other neurological problems is reported with valproate exposure during the first trimester (Viguera and Cohen 1998). Reports have suggested that overall lithium is not a high-risk teratogen. For example, in a prospective study of women who took lithium during the first trimester (*N* = 148) and control subjects matched for age, rates of major malformations did not differ between the lithium and control groups (2.8% and 2.4%, respectively), although women in the lithium group were significantly more likely to be smokers (Jacobson et al. 1992). The authors concluded that pregnant women with mood disorders may continue taking lithium, provided that adequate screening of level II ultrasounds and fetal echocardiography are performed. Maternal serum α-fetoprotein screening is also recommended for women taking mood stabilizers during pregnancy (American Psychiatric Association 2002). Also, in a cohort study (*N* = 350), 7% of the women who used lithium early in pregnancy had infants with cardiac defects, although none had Ebstein's anomaly (Kallen and Tandberg 1983). However, there was no statistically significant difference between delivery outcome with lithium and that with other psychotropics.

Lithium today is considered a first-line alternative for the treatment of bipolar disorder during pregnancy. However, many women may want to discontinue psychotropic medications during pregnancy. Viguera et al. (2000) found that rates of relapse were similar in pregnant and nonpregnant women but higher in the postpartum period. During the postpartum period, significantly more women experienced a relapse after lithium discontinuation (followed by 40 weeks of euthymia) compared with nonpregnant patients matched for time after discontinuation (70% vs. 24%). Despite continued treatment with lithium, three of nine (33%) women who were maintained on lithium during pregnancy experienced a relapse postpartum, underscoring the high risk of postpartum relapse in women with bipolar disorder. This high risk has led to experts in the field recommending prophylactic treatment with a mood stabilizer for postpartum women (L. S. Cohen et al. 1995). Newport et al. (2005) studied lithium levels in maternal blood and umbilical cord blood and found that lithium equilibrates across the placenta. They observed that infants with higher lithium levels experienced more neonatal complications and suggested withholding lithium therapy 24–48 hours before an anticipated delivery to minimize risk to the baby.

Despite a general paucity of documented adverse effects to breast-feeding infants of mothers taking lithium, the American Academy of Pediatrics has contraindicated lithium use in breast-feeding women

(Chaudron and Jefferson 2000). As reviewed by Chaudron and Jefferson (2000), lithium is passed on to breast-feeding infants and is found in breast milk and infant serum. Concentration in breast milk ranges from 24% to 72% of maternal serum concentration. A wide range of infant serum levels has been reported (5%–200% of mother's level), and two cases of adverse events in breast-feeding infants have been published. Burt et al. (2001) found documentation of only 13 infants exposed to lithium in breast milk—4 had no adverse effects; clinical status was not reported for 8; and 1 infant who was exposed both in utero and while breast feeding had serious adverse reactions, including cyanosis, heart murmur, and hypotonia (Tunnessen and Hertz 1972). Viguera et al. (2007) recently assessed babies who were breast fed while their mothers were treated with lithium monotherapy for bipolar disorder. They assessed 10 mother–baby pairs. Serum lithium levels in the babies ranged from 0.09 to 0.3 mEq/L (mean 0.16). Transient elevations in infant thyroid-stimulating hormone (TSH), blood urea nitrogen (BUN), and creatinine level were observed without evident long-term effects. They recommended that breast feeding in the context of lithium therapy may be considered reasonable for a healthy infant when the mother's bipolar disorder is clinically stable, lithium monotherapy or a simple medication regimen is being utilized, and the pediatrician supports breast feeding while the mother is treated with lithium. They recommend monitoring of serum lithium, TSH, BUN, and creatinine level in the infant immediately postpartum, 4–6 weeks after delivery, and then every 8–12 weeks while the mother is breast feeding.

SIDE EFFECTS AND TOXICOLOGY

> Psychological issues ultimately proved far more important than side effects in my prolonged resistance to lithium. I simply did not want to believe that I needed to take medication. I had become addicted to my high moods. . .. I couldn't give them up. (Jamison 1995, pp. 98–99)

Laboratory Monitoring

Before lithium therapy is started, medical history should be obtained, as well as baseline renal laboratory tests (BUN, creatinine level), thyroid function tests, and an electrocardiogram for patients older than 40 years (American Psychiatric Association 2002). The American Psychiatric Association practice guideline suggests that renal function should be assessed every 2–3 months and thyroid function tested once or twice during the first 6 months of treatment. After the first 6 months, renal laboratory tests and thyroid function tests should be monitored every 6–12 months or whenever clinically indicated (American Psychiatric Association 2002).

Side Effects

Cognitive side effects and weight gain have been reported to be the most disturbing side effects to patients receiving lithium maintenance treatment, whereas self-reported noncompliance was mostly associated with effects on cognition and coordination (Gitlin et al. 1989). Weight gain may be a greater risk for patients who are obese before commencement of lithium treatment, compared with normal-weight individuals (Bowden et al. 2006). Keck et al. (1996) reported that 64% of the patients hospitalized for bipolar disorder were noncompliant within the month prior to admission. Lack of compliance was associated with mania severity and polypharmacy (Keck et al. 1996). Most patients who receive treatment with lithium will experience signs or symptoms of toxicity at some time (Groleau 1994). However, a minority (27.8%) of patients with excessive levels of lithium (≥1.5 mmol/L) manifested symptoms of toxicity when hospitalized (Webb et al. 2001). Women and the elderly were most likely to have excessive levels.

Neurotoxicity

Neurotoxicity, delirium, and encephalopathy have been reported with lithium use. Specific populations have been noted to be at higher risk. Also, certain circumstances such as concomitant ECT or other psychotropics—especially neuroleptics—have been implicated in increasing the risk of such adverse

effects of lithium treatment. West and Meltzer (1979) reported five cases in which patients experienced severe neurotoxic reactions, with lithium levels ranging from 0.75 to 1.7 mEq/L, and suggested that those with greater levels of psychotic symptomatology and anxiety may be at higher risk for neurotoxic reactions.

Neurotoxic reactions are potentially irreversible. Permanent neurological deficits have been reported after episodes of lithium intoxication (Apte and Langston 1983; Donaldson and Cuningham 1983). These have included deficits in recent memory, ataxia, and movement disorders. Early hemodialysis may help prevent permanent sequelae. Donaldson and Cuningham (1983) also reported persistent neurological sequelae of lithium toxicity involving multiple sites within the nervous system. Himmelhoch et al. (1980) found a greater incidence of neurotoxicity secondary to lithium treatment in the elderly. Squire et al. (1980) reported that lithium treatment may adversely affect fine motor skills. In a double-blind, placebo-controlled crossover study (N = 16), patients were given lithium or placebo for 2 weeks after a washout period and were then crossed over to placebo or lithium, respectively. Neuropsychiatric test results showed a slowing of performance rate. Stoll et al. (1996) reported a case series in which 7 patients who experienced lithium-associated cognitive deficits improved when switched to treatment with divalproex sodium.

Productivity and Creativity

al. 1996). The combination of lithium and valproate is a strategy in the treatment of mania refractory to monotherapy with either lithium or valproate (Frances et al. 1996). Double-blind, placebo-controlled data support that lithium plus valproate is more effective in relapse prevention than lithium alone (Solomon et al. 1997). The combination appears to confer benefit in mania, bipolar depression, and rapid cycling (Mitchell et al. 1994; Schaff et al. 1993; Sharma and Persad 1992; Sharma et al. 1993). Interactions may include additive side effects, such as sedation, tremor, or weight gain, but the pharmacokinetics of lithium are not altered by the addition of valproate (Granneman et al. 1996).

Lithium and carbamazepine also have been combined for bipolar disorder refractory to lithium alone (Frances et al. 1996) and may confer a more rapid antimanic effect than lithium alone for some patients (Di Costanzo and Schifano 1991; Kramlinger and Post 1989). This combination is better tolerated than and at least as effective as the combination of lithium and a typical antipsychotic (Shukla et al. 1985; Small et al. 1995). The combination also may work synergistically in the prophylaxis of mood episodes (Kishimoto 1992). Neurotoxicity, especially in patients with central nervous system deficits, may be an increased risk with the combination of lithium and carbamazepine (Chaudhry and Waters 1983; Shukla et al. 1984). Neurotoxic and other adverse reactions have been associated with the concomitant administration of lithium with calcium channel blockers (Dubovsky et al. 1987; Finley et al. 1995; Helmuth et al. 1989; Wright and Jarrett 1991).

Although many investigators have reported the safe and efficacious results of combining lithium and typical antipsychotics (Baastrup et al. 1976; Bigelow et al. 1981; Carman et al. 1981; Garfinkel et al. 1980; Ghadirian et al. 1989; Goldney and Spence 1986; Juhl et al. 1977; Krishna et al. 1978; Loew 1986; Miller and Menninger 1987; Perenyi et al. 1983), use of lithium with "typicals" may increase the occurrence of side effects, including neurotoxicity and even tardive dyskinesia (Byrne et al. 1994; W. J. Cohen and Cohen 1974; Dinan and Kohen 1989; Loudon and Waring 1976; Mani et al. 1996; Mann et al. 1983; Marhold et al. 1974; Menes et al. 1980; Miller et al. 1986; Perenyi et al. 1984; Spring 1979; Spring and Frankel 1981). Goodwin and Jamison (1990) recommended that when incorporating a typical antipsychotic into a regimen of lithium therapy, the antipsychotic should be used in lower doses and the lithium levels should be maintained below 1.0 mEq/L.

The use of lithium with atypical antipsychotics also may result in adverse reactions. Clozapine and lithium, when used concomitantly, have been reported to be efficacious for refractory bipolar disorder (Fuchs 1994; Puri et al. 1995; Suppes et al. 1994), but adverse reactions, including diabetic ketoacidosis, neuroleptic malignant syndrome, and neurological side effects, also have been reported (Blake et al. 1992; G. Garcia et al. 1994; Lemus et al. 1989; Peterson and Byrd 1996; Pope et al. 1986). Some investigators have reported safe and effective use of risperidone and lithium (Ghaemi et al. 1997; Tohen et al. 1996), although adverse effects, including fever, increased white blood cell counts and creatine phosphokinase levels, and delirium, also have been reported (B. Chen and Cardasis 1996; Swanson et al. 1995).

Preliminary data suggest that the combination of lithium and olanzapine is efficacious and well tolerated in acute mania (Madhusoodanan et al. 2000; Sanger et al. 2001). Gabapentin is also used adjunctively in the treatment of bipolar disorder, and because gabapentin has no known drug interactions, it is likely safe with lithium use (Frye et al. 1998; Vollmer et al. 1986). Benzodiazepines are not especially problematic when used with lithium. Sachs et al. (1990a, 1990b) reported that benzodiazepines can be used successfully instead of antipsychotic medications in some patients with bipolar disorder. Others have shown that clonazepam and lorazepam are efficacious and well tolerated with lithium in the treatment of acute mania (Adler 1986; Modell et al. 1985).

Lithium and Antidepressants

Lithium is often used concomitantly with antidepressants in the treatment of bipolar depression and refractory unipolar depression. Serotonin syndrome—a constellation of mental status and behavioral

changes (either agitation or sedation), motor symptoms (restlessness, weakness, hyperreflexia, or ataxia), and autonomic dysfunction (nausea and/or vomiting, dizziness, sweating, fever) (Lejoyeux et al. 1994)—has been reported with the use of lithium and serotonergic antidepressants, including fluoxetine (Karle and Bjorndal 1995; Muly et al. 1993), paroxetine (Sobanski et al. 1997), venlafaxine (Mekler and Woggon 1997), and fluvoxamine (Ohman and Spigset 1993). Retrospective evaluation of clinical records by Fagiolini et al. (2001) suggested the development of serotonin syndrome in 4 of 17 (24%) patients receiving the combination of lithium and paroxetine.

Lithium and Electroconvulsive Therapy

Patients who undergo concurrent ECT and lithium treatment may experience neurotoxic reactions, which include delirium and memory deficits (Ayd 1981; DePaulo et al. 1982; El-Mallakh 1988; Jefferson et al. 1987; Mielke et al. 1984). Additionally, Small et al. (1980) retrospectively compared adverse reactions of patients who received concurrent lithium and ECT with those of patients who received ECT alone. The group that received both ECT and lithium experienced more memory loss than did the group undergoing ECT without lithium treatment. However, Himmelhoch and Neil (1980) found similar outcomes in 21 patients receiving ECT and lithium and in age- and sex-matched control subjects receiving ECT alone. They did not find differences in adverse reactions, including post-ECT confusion. To minimize adverse reactions, Ayd (1981) recommended that lithium be discontinued at least 2 days prior to ECT and restarted 2–3 days after the last treatment.

Lithium and Nonpsychotropic Medications

When lithium is used with concurrent nonsteroidal anti-inflammatory drugs, signs and symptoms of toxicity and lithium levels must be monitored more carefully because nonsteroidal anti-inflammatory drugs increase the risk of toxicity (Johnson et al. 1993). Because lithium excretion relies on renal clearance, diuretic medications may affect lithium levels, depending on their site of action. Thiazide diuretics trigger a compensatory increase in reabsorption in the proximal tubule and lead to elevations in lithium levels, whereas loop diuretics do not promote lithium reabsorption and do not greatly affect lithium levels (Finley et al. 1995). Osmotic diuretics enhance lithium excretion and may serve to counteract lithium toxicity, and either no change or a slight increase in lithium levels has been reported with potassium-sparing diuretics. Angiotensin-converting enzyme inhibitors may raise lithium levels (DasGupta et al. 1992; Finley et al. 1996). Serum lithium levels may increase in the context of sodium restriction (Bennett 1997).

CONCLUSION

Lithium is an important option in the evidence-based rational treatment of bipolar disorder. Bipolar disorder is a mental illness that affects between 1% and 5% of the population (Akiskal et al. 2000). Bipolar disorder causes significant morbidity and mortality, and the diagnosis of bipolar disorder carries a high risk for suicide. Of patients with bipolar disorder, 25%–50% attempt suicide and an estimated 19% complete suicide (Goodwin and Jamison 1990).

Lithium has been shown to be effective for acute mania and bipolar depression and as a prophylactic treatment for bipolar disorder. Some data suggest that conditions such as comorbid neurological illness and mixed episodes favor other mood stabilizers rather than lithium. Evidence also suggests that lithium can play a role in the treatment of refractory unipolar depression, aggression, and personality disorders. Lithium may be less risky than anticonvulsants in pregnancy. We seek new treatments in our field and hope that they will be more efficacious and better tolerated than our "old" medications. At present, lithium remains an important treatment option.

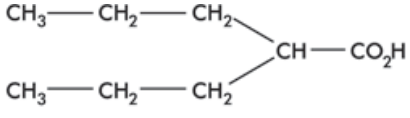
Chapter 36. Valproate

HISTORY AND DISCOVERY



Valproic acid was first synthesized by Burton in the United States in 1882 and subsequently was used as an organic solvent. The drug's antiepileptic properties were discovered serendipitously by Meunier in 1963 in France. Meunier used valproic acid as a vehicle for other compounds that were being screened for antiepileptic activity. He found that compounds that did not have antiepileptic properties when administered alone inhibited seizure activity when dissolved in valproic acid and concluded that the antiepileptic activity was due to the solvent, valproic acid, rather than to the test drugs (Bowden and McElroy 1995; Fariello and Smith 1989; Meunier et al. 1975).

Valproate was the first alternative mood stabilizer to be studied, with Lambert's first research published in 1966 (Lambert et al. 1966). Valproate was first introduced as an antiepileptic in France in 1967. It has been used in Holland and Germany since 1968 and in the United Kingdom since 1973, and it became available in the United States in 1978. An enteric-coated formulation, divalproex sodium, was introduced to the U.S. market in 1983. A formulation consisting of a capsule containing coated particles of divalproex sodium was introduced in 1989. An extended-release formulation of divalproex was approved for migraine in 2001 and mania in 2006. Valproate was approved for treatment of mania in the United States in 1995. Valproate, either as divalproex or as other formulations, is now approved for treatment of mania in most developed countries.

STRUCTURE–ACTIVITY RELATIONS

Valproic acid (dipropylacetic acid) is an eight-carbon, branched-chain carboxylic acid that is structurally distinct from other antiepileptic and psychotropic compounds (Bocci and Beretta 1976; Levy et al. 2002) (Figure 36–1). Although straight-chain acids have little or no antiepileptic activity, other branched-chain carboxylic acids have potencies similar to that of valproate in antagonizing pentylenetetrazole-induced seizures. However, increasing the number of carbon atoms to nine introduces marked sedative properties. The primary amide of valproic acid, valpromide, has been reported to be about twice as potent as the parent compound.

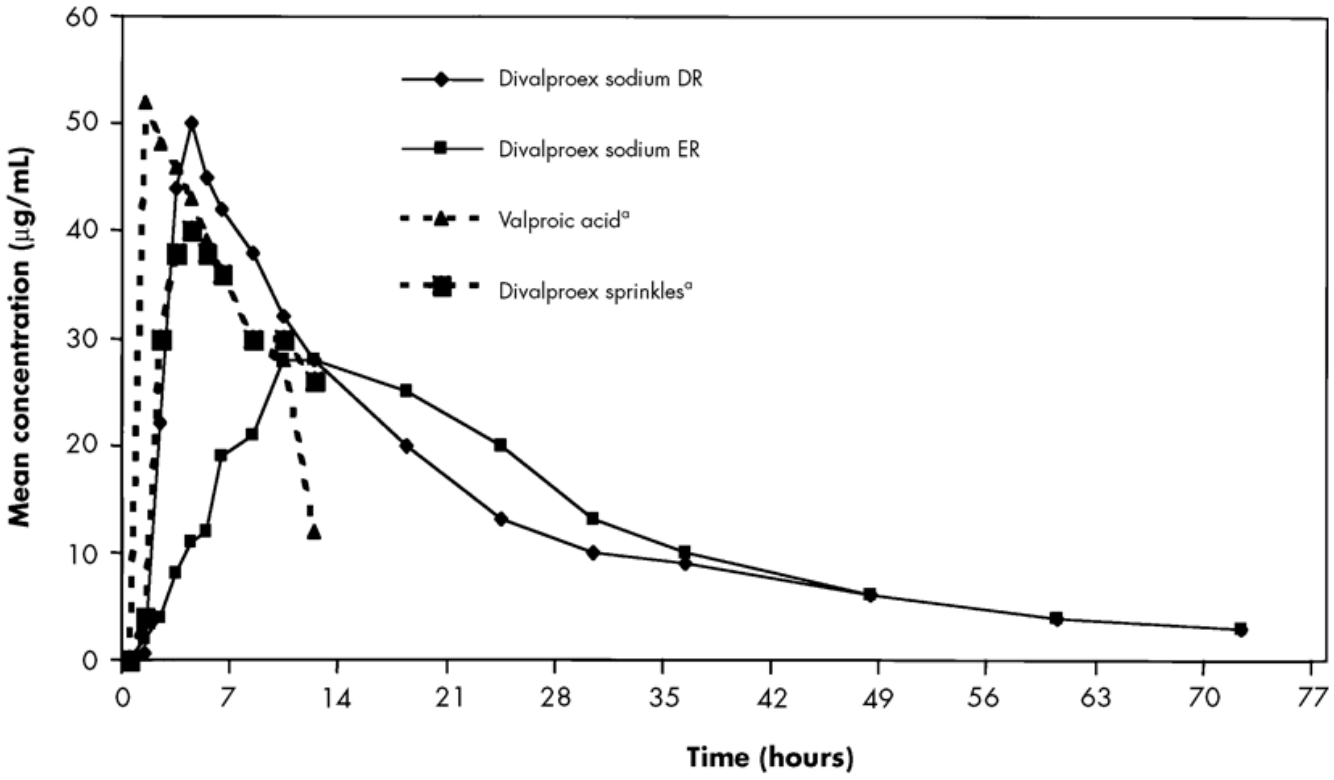
PHARMACOLOGICAL PROFILE

Valproate blocks pentylenetetrazole-induced and maximal electroshock seizures in a variety of animals and suppresses secondarily generalized seizures without affecting focal activity in chemically lesioned animals (Fariello and Smith 1989). Valproate also has antikindling properties, preventing the spread of epileptiform activity in cats without affecting focal seizures (Leveil and Nanquet 1977).

Studies in epilepsy and bipolar disorder indicate that divalproex causes a reduction in plasma levels of γ-aminobutyric acid (GABA) and that plasma GABA levels positively correlate with the degree of improvement in manic symptomatology (Brennan et al. 1984; Emrich et al. 1981). Animal studies also indicate that chronic valproate increases the expression of mRNA encoding the 67-kilodalton isoform of glutamate decarboxylase (GAD_{67}) in the brain, thereby facilitating GABAergic transmission (Tremolizzo et al. 2002). Valproate is incorporated into neuronal membranes in a saturable manner and appears to displace naturally occurring branched-chain phospholipids (Siafaka-Kapadai et al. 1998). Chronic valproate reduces protein kinase C (PKC) activity in manic patients (Hahn et al. 2005). Elevated PKC activity has been associated with manic patients and in animal models for mania (Einat and Manji 2006). Valproate inhibits glycogen synthase kinase 3 (GSK-3) at concentrations present therapeutically. The effect is indirect, linked to its capability to upregulate gene expression through inhibition of histone deacetylase (Harwood and Agam 2003). In laboratory animals, valproate activates the extracellular signal-regulated kinase (ERK) pathway (Einat et al. 2003). Valproate increases the expression of the cytoprotective protein B-cell lymphoma/leukemia-2 gene (*bcl-2*) in the central nervous system in vivo and in cells of human neuronal origin (Gray et al. 2003). Valproate provided antioxidant effects, reversing early DNA damage caused by amphetamine in an animal model of mania (Andreazza et al. 2007). Valproate and lithium both reduce inositol biosynthesis. However, the mechanism of valproate action is unique, resulting from decreased myo-inositol 1-phosphate synthase inhibition (Shaltiel et al. 2004). Valproate and lithium both lengthen the period of circadian rhythms and increase arrhythmicity in *Drosophila.* This action of the two drugs is

of interest given recent data implicating sets of genes associated with circadian rhythmicity in bipolar disorders (Dokucu et al. 2005). Therapeutic doses of either valproate or lithium increase the antiapoptotic protein *bcl-2* in anterior cingulate cortex, potentially providing a buffer against the destructive effects of increased intracellular Ca^{2+} in bipolar disorder (Quiroz et al. 2008).

Despite primary differences in the initial modes of action of valproate and lithium, it is noteworthy that valproate and lithium have substantial overlapping effects on neuronal systems involved in maintaining mood stability and alertness that have not been observed in studies of similar systems with carbamazepine or atypical antipsychotic drugs. Whereas several of the above-reviewed systems are impacted by both lithium and valproate, only valproate inhibits histone deacetylase, which in turn results in a gradual increase in the phosphorylation of Akt and GSK-3β (Harwood and Agam 2003). Valproate enhances acetylated histone content, thereby preventing methionine-induced reelin promoter hypermethylation and normalizing behavioral responses in a mouse model for schizophrenia-like behavior (Tremolizzo et al. 2005). Recent study of valproate as a cancer chemotherapeutic agent may also be stimulated by its effects on cell proliferation through inhibition of histone deacetylase (Andratschke et al. 2001).



Valproate increased corticotropin-releasing factor (CRF) mRNA expression in the cortex and reduced CRF type 1 receptor (CRF_1) binding in the amygdala and cortex of nonstressed rats, suggesting that one of valproate's effects in the brain is to dampen tone in this pathway, which is associated with stress-linked psychopathology (Gilmor et al. 2003).

PHARMACOKINETICS AND DISPOSITION

Valproate is commercially available in the United States in five oral preparations: 1) divalproex sodium, an enteric-coated, stable-coordination compound containing equal proportions of valproic acid and sodium valproate in a 1:1 molar ratio; 2) valproic acid; 3) sodium valproate; 4) divalproex sodium sprinkle capsule (containing coated particles of divalproex sodium), which can be ingested intact or pulled apart and contents sprinkled on food; and 5) an extended-release form of divalproex that provides once-daily dosing and a substantially flatter peak-to-trough ratio. Sodium valproate is available for intravenous use and, as such, has been demonstrated to provide reduction in manic symptoms within 1 day or less (Grunze et al. 1999). Valproate can also be compounded in suppository form for rectal administration. The valproate ion is the common compound in plasma.

The bioavailability of valproate approaches 100% with all preparations (Levy et al. 2002; Penry and Dean 1989; Wilder 1992). All preparations taken orally, except divalproex sodium, are rapidly absorbed after oral ingestion. Sodium valproate and valproic acid attain peak serum concentrations within 2 hours. Divalproex sodium reaches peak serum concentrations within 3–8 hours. The extended-release form of divalproex has an earlier onset of absorption than divalproex sodium regular-release tablets and approximately a 20% smaller difference in trough and peak serum levels than regular-release divalproex (Figure 36–2). Absorption can also be delayed if the drug is taken with food.

Valproate is highly protein bound, predominantly to serum albumin and proportional to the albumin concentration. Although patients with low levels of albumin have a higher fraction of unbound drug, the steady-state level of total drug is not altered. Only the unbound drug crosses the blood–brain barrier and is bioactive. Thus, when valproate is displaced from protein-binding sites through drug interactions, the total drug concentration may not change; however, the pharmacologically active unbound drug does increase and may produce signs and symptoms of toxicity. Moreover, when the plasma concentration of valproate increases in response to increased dosing, the amount of unbound (active) valproate increases disproportionately and is metabolized, with an apparent increase in clearance of total drug, yielding lower-than-expected total plasma concentrations (Levy et al. 2002; Wilder 1992) (Figure 36–3). In addition, valproate protein binding is increased by low-fat diets and decreased by high-fat diets. Because of lower serum protein levels, women and elderly patients will generally have a higher proportion of the active free moiety.

The concentration range generally required for good clinical effect in mania is approximately 45 to 125 μg/mL (Bowden et al. 1996). Patients who tolerate higher serum levels, up to around 125 μg/mL, may have greater improvement (Allen et al. 2006). One open report suggests that patients with bipolar II conditions and cyclothymia may respond to serum valproate concentrations of less than 50 μg/mL (Jacobsen 1993).

Valproate is metabolized primarily in the liver by glucuronidation. In addition, oxidative pathways yield a large number of metabolites, some of which have antiepileptic and/or toxic effects (Bocci and Beretta 1976; Levy et al. 2002; Penry and Dean 1989; Wilder 1992) (Figure 36–4). The oxidative pathways are mitochondrial β-oxidation to 3-hydroxyvalproate, 3-oxo-valproate, and 2-en-valproate; and the cytochrome P450 microsomal metabolism to the toxic 4-en- and 2,4-en metabolites. Less than 3% of valproate is excreted unchanged in the urine and feces. Valproate's elimination half-life is typically 5–20 hours and can be altered by agents that affect the mitochondrial and/or microsomal enzyme systems responsible for its metabolism.

VPA is metabolized within the mitochondria by the β-oxidative pathway, which metabolizes medium- and long-chain fatty acids. This is the major metabolic pathway used in patients taking VPA as monotherapy. VPA is also metabolized by the microsomal cytochrome P450 pathway, which occurs outside the mitochondria; metabolism via this pathway is increased when VPA is administered in combination with enzyme-inducing drugs (e.g., carbamazepine). 3 OH-VPA = 3-hydroxyvalproate; 3-OXO-VPA = 3-oxo-valproate; Δ^2 VPA = 2-en-valproate metabolite; Δ^4 VPA = 4-en-valproate metabolite; $\Delta^{2,4}$ VPA = 2,4-en-valproate metabolite; $t_{½}$ = half-life.

Treatment with valproate for bipolar disorder is usually begun at a dosage of 15–20 mg/kg/day. The drug can be "orally loaded" at 20–30 mg/kg/day in patients with acute mania to induce more rapid response. The dosage of valproate is increased according to the patient's response and side effects, usually by 250–500 mg/day every 1–3 days, to serum concentrations of 45–125 μg/mL. Of note, sedation, increased appetite, and reduction in white blood count and platelet count all become more frequent at serum concentrations above 100 μg/mL (Bowden 2000). During maintenance treatment, bipolar I patients whose serum levels were between 75 and 100 μg/mL had significantly longer time to intervention for a developing mood episode than did patients with serum levels either lower or higher than this range (Keck et al. 2005).

INDICATIONS AND EFFICACY

The indications for valproate that are currently recognized by the U.S. Food and Drug Administration (FDA) are for the treatment of manic episodes associated with bipolar disorder; for sole and adjunctive therapy in the treatment of simple and complex absence seizures; for adjunctive therapy in multiple seizure types, including absence seizures; and for prophylaxis of migraine. Controlled studies have also shown that valproate is effective in prevention of recurrence of mania in bipolar disorder (Tohen et al. 2003) and in prolongation of the depression-free period compared with lithium (Gyulai et al. 2003). Controlled studies additionally indicate that valproate is effective in generalized epilepsies, including generalized tonic–clonic and myoclonic seizures, as well as in secondarily generalized tonic–clonic seizures, infantile spasms, photosensitive epilepsy, and febrile seizures (Bourgeois 1989; Rimmer and Richens 1985).

Use in Bipolar Disorder

Acute Bipolar Mania

Numerous open studies and controlled trials (five placebo-controlled, one haloperidol-controlled, one lithium-controlled, and one placebo- and lithium-controlled) indicate that valproate is effective in the treatment of acute mania (Bowden et al. 1994; McElroy et al. 1993). In the controlled trials (Bowden et al. 1994, 2006; Brennan et al. 1984; Emrich et al. 1985; Freeman et al. 1992; McElroy et al. 1996; Pope et al. 1991), valproate was superior to placebo and comparable to lithium and haloperidol in the

short-term treatment of acute mania. The most recent placebo-controlled study indicated that patients with more severe manic symptoms experienced greater benefits from valproate relative to placebo compared with patients with milder manic symptomatology (Bowden et al. 2006). In these studies, the antimanic response to valproate occurred as early as 5 days following initiation of treatment.

In an open-label, rater-blind study of valproate administration via an oral loading dosage of 20 mg/kg/day to 19 patients with acute mania, 10 (53%) of the patients had a significant response within 5 days of treatment, with minimal side effects (Keck et al. 1993). Similarly, in a controlled comparison study with haloperidol, divalproex administered at 20 mg/kg/day produced rapid antimanic and antipsychotic effects comparable to those of haloperidol (McElroy et al. 1996). Valproate and carbamazepine were compared in a small (n = 30) blinded, randomized study in acute mania (Vasudev et al. 2000). Valproate provided greater reduction in mania scores, produced earlier response, and was associated with fewer adverse effects than carbamazepine.

Intravenous valproate infused as 600 mg over 20 minutes yielded rapid improvement in 4 of 5 manic patients (Grunze et al. 1999). In the aggregate, studies of the past decade have extended the evidence of the efficacy of valproate and the breadth of circumstances in which it can be effectively employed. The area of weakness in studies for valproate, as well as other antimanic agents, is that there have been only open case series for patients with hypomania or cyclothymia (Jacobsen 1993).

Adjunctive Regimens in Mania

Valproate has been studied in an add-on design in mania with consistent evidence that addition either of valproate to an antipsychotic (Muller-Oerlinghausen et al. 2000) or of an antipsychotic (olanzapine, quetiapine, risperidone, haloperidol) to valproate (or lithium) resulted in approximately 20% higher rates of antimanic response than with the antipsychotic or valproate alone (Tohen et al. 2002; Yatham 2003, 2005).

Patients treated with valproate plus lithium were significantly less likely to relapse over the course of a year than were patients treated with lithium. Side effects were more common with the combination regimen (Solomon et al. 1997).

One of the combination studies enrolled both patients who had received treatment with either valproate or lithium at an adequate dose for 2 weeks or longer and were still manic and patients who were manic without treatment, in which case both risperidone or haloperidol and either lithium or valproate were started concurrently. No advantage for the combination treatment occurred in the cotherapy group, whereas patients who had demonstrated unresponsiveness to valproate or lithium showed the advantage of the add-on therapy. The results suggest that in most circumstances combination therapy should be limited to patients who fail to respond to a relatively short period of adequate treatment with a first drug before adding the second (Sachs et al. 2002).

Maintenance Treatment of Bipolar Disorder

Several recent studies address the question of maintenance of effect in mania. A 12-week randomized, blinded comparison of valproate and olanzapine showed equivalent efficacy on mania for the two treatments (Zajecka et al. 2002). A 47-week study of the two drugs reported low rates of completion for both treatments (15% vs. 16%), with earlier symptomatic remission with olanzapine but equivalent efficacy for the two drugs over the remaining portion of the study. For both drugs, patients who were in remission at the end of week 3 of treatment were significantly more likely to complete the 47-week trial than those not in remission (divalproex: 26.2% vs. 11.1%; olanzapine: 20.3% vs. 10.6%; P = 0.001). This finding indicates that acute treatment response to a drug (either valproate or olanzapine) during a manic episode is predictive of effective treatment with the same drug in maintenance therapy. In both studies, weight gain was greater with olanzapine than with divalproex, and divalproex was associated with a significant reduction in cholesterol levels, compared with an increase in cholesterol levels with olanzapine (Tohen et al. 2003; Zajecka et al. 2002).

One large (n = 372) double-blind, placebo-controlled maintenance monotherapy study of valproate has been published (Bowden et al. 2000). Patients who recovered with open treatment with either divalproex or lithium were randomly assigned to maintenance treatment with divalproex, lithium, or placebo. The divalproex group did not differ significantly from the placebo group in time to any mood episode (P = 0.06), in part because the rate of relapse into mania with placebo was lower than anticipated. On most secondary outcome measures, divalproex was superior to placebo, with lower rates of discontinuation for either any recurrent mood episode or a depressive episode (Bowden 2004). Divalproex was superior to lithium on some comparisons, including longer duration of successful prophylaxis in the study and less deterioration in depressive symptom scores. Among the subset of patients treated with divalproex in the open acute phase, those subsequently randomized to divalproex had significantly longer times to recurrence of any mood episode (P = 0.05) or a depressive episode (P = 0.03), and the proportion of patients who completed the 1-year study without developing either a manic or a depressive episode was significantly higher for divalproex than for placebo (41% vs. 13%; P = 0.01). This is the only study published to date that has allowed a statistical test of the relationship between acute-episode response to treatment and maintenance treatment outcomes (Bowden et al. 2000). A secondary post hoc review of the study employing relative risk analysis found that patients treated with divalproex were significantly less likely than those treated with placebo to have prematurely left the study because of a mood episode (relative risk [RR] = 0.63, 95% confidence interval [CI] = 0.44–0.90) (Macritchie et al. 2001). A post hoc analysis of time to any mood episode or early discontinuation for any reason, a measure of effectiveness that has been incorporated in recent maintenance studies in bipolar disorder, indicated a significant advantage for divalproex over lithium (P >0.004) (Bowden 2003a).

A randomized open comparison of valpromide (the primary amide of valproic acid) and lithium for an 18-month period reported good efficacy for both drugs, with somewhat more favorable results among valpromide-treated patients (Lambert and Venaud 1992). The mean number of recurrent affective episodes per patient during the maintenance period was 0.61 in the lithium-treated group and 0.51 in the valpromide-treated group.

A separate study comparing valproate and lithium in a randomized, blinded trial of rapid-cycling patients reported that only one-quarter of patients enrolled met criteria for an acute bimodal response to either drug, with fewer than 25% of those randomized retaining benefits without relapse for the 20-month maintenance period. The results indicate that monotherapy regimens with either mood stabilizer are unlikely to be effective in any more than a small minority of rapid-cycling patients (Calabrese et al. 2005).

Acute Bipolar Depression

An 8-week randomized, placebo-controlled, blinded study reported that divalproex-treated subjects experienced significantly greater improvement than placebo-treated patients in both depressive and anxious symptomatology, based on Hamilton Rating Scale for Depression (Ham-D) and Hamilton Anxiety Scale (Ham-A) scores (Davis et al. 2005). In a 6-week randomized, blinded study in bipolar depression, divalproex was superior to placebo, with a large effect size advantage (Cohen's d = 0.81). Primary improvement was on core mood symptoms rather than on anxiety or insomnia (Ghaemi et al. 2007). In an 8-week double-blind study of bipolar I or II depressed patients, 43% of patients treated with divalproex recovered, compared with 27% of patients treated with placebo. However, change in the total Ham-D score did not differ significantly between divalproex and placebo, although the depressed mood item favored divalproex at weeks 2, 4, and 5 (Sachs et al. 2001). In a 1-year randomized, double-blind study of initially manic bipolar patients, divalproex was more effective than lithium or placebo in delaying time to clinical depression. In those subjects who developed depression, divalproex plus paroxetine or sertraline was superior to either antidepressant alone in treatment of the depression (Gyulai et al. 2003).

In summary, several relatively small studies suggest some antidepressant properties for valproate both in acute depression and in prophylaxis; however, adequately powered studies have not yet been conducted.

Bipolar Disorder in Children and Adolescents

Open trials of valproate report moderate to marked improvement in manic youth ages 8–18 years (Deltito et al. 1998; Mandoki 1993; Papatheodorou and Kutcher 1993; Wagner et al. 2002). Kowatch et al. (2000) studied 42 bipolar I manic patients (ages 9–18 years) who were treated for 6 weeks with divalproex, lithium, or carbamazepine in a randomized open study. Overall, 61% achieved 50% or greater improvement, which did not differ significantly across the groups. The effect size for improvement was greater for divalproex-treated patients than for lithium-treated or carbamazepine-treated patients (divalproex = 1.63, lithium = 1.06, carbamazepine = 1.00). A 6-month open study of valproate as monotherapy for 34 pediatric subjects with mixed mania reported high treatment completion rates and effectiveness of the drug (Pavuluri et al. 2005). Because the available data are limited to findings from open trials, valproate's comparative efficacy and effectiveness remain to be established.

One double-blind, randomized, placebo-controlled study has been conducted in youth ages 8–10 years who met criteria for oppositional defiant disorder or conduct disorder and had experienced temper and mood liability but did not meet the full criteria for bipolar disorder. By the end of phase 1, 8 of 10 patients who received divalproex had responded, compared with none on placebo. Of the 15 patients who completed both phases, 12 had superior responses to divalproex (Donovan et al. 2000).

Bipolar Disorder in the Elderly

Open trials (Narayan and Nelson 1997; Risinger et al. 1994) and one randomized, placebo-controlled study (Porsteinsson et al. 2001) reported benefits of valproate for irritable, agitated symptoms of dementia and for mania in elderly patients with bipolar disorder (Kahn et al. 1988; McFarland et al. 1990). The studies are difficult to summarize, as the authors did not utilize consistent terminology to report the behavioral disturbances of interest. For example, the terms *behavioral disturbance, aggression, agitation, hostility,* and *impulsivity* have all been used to describe effects of valproate on a symptom set that deals with the hyperactive and irritable dimensions of mania in the elderly (Narayan and Nelson 1997; Tariot et al. 1998). In a randomized, blinded study of 56 nursing home patients with agitation and dementia treated with either placebo or individualized doses of divalproex, when several covariates were taken into account, the drug/placebo difference in Brief Psychiatric Rating Scale Agitation scores became statistically significant (P = 0.05). Sixty-eight percent of patients on divalproex were rated as showing reduced agitation on the Clinical Global Impression Scale, versus 52% on placebo (P = 0.06 in the adjusted analysis). Side effects occurred in 68% of the divalproex group versus 33% of the placebo group (P = 0.03) and were generally rated as mild. This placebo-controlled study, despite some limitations, suggests possible short-term efficacy, tolerability, and safety of divalproex for agitation in dementia and supports further placebo-controlled studies (Porsteinsson et al. 2001). Patients with dementia are most frequently institutionalized for agitation and behavioral disturbances. A smaller randomized, placebo-controlled study using a fixed dose (valproate 480 mg/day) that may have been inadequate failed to find any difference between valproate and placebo groups.

Bipolar Disorder With Alcoholism

Bipolar disorder is often associated with comorbid substance use disorders, particularly alcoholism. In the largest prospective,

blinded, placebo-controlled study, 59 bipolar I patients with alcohol dependence were treated with lithium carbonate and psychosocial interventions for 24 weeks, with half randomly assigned to receive adjunctive valproate. The addition of valproate was associated with significantly fewer heavy drinking days, fewer drinks per heavy drinking day, and fewer drinks per drinking day. Higher serum valproate concentrations were correlated with improved alcohol use outcomes. Both manic and depressive symptoms improved equivalently (Salloum et al. 2005).

In a 12-week double-blind, placebo-controlled trial, divalproex was associated with a significantly smaller percentage of individuals relapsing to heavy drinking, but there were no significant differences in other alcohol-related outcomes. There were significantly greater decreases in irritability in the divalproex-treated group and a trend toward greater decreases on measures of lability and verbal assault. There were no significant between-group differences on measures of impulsivity (Brady et al. 2002).

Bipolar Disorder Comorbid With Borderline Personality Disorder

Frankenburg and Zanarini (2002) conducted a placebo-controlled, double-blind study of divalproex sodium in 30 female subjects ages 18–40 years who met Revised Diagnostic Interview for Borderlines (Zanarini et al. 1989) and DSM-IV (American Psychiatric Association 1994) criteria for borderline personality disorder and DSM-IV criteria for bipolar II disorder. Subjects were randomly assigned to divalproex or placebo in a 2:1 manner. Treatment duration was 6 months. Divalproex was significantly superior to placebo in diminishing interpersonal sensitivity and anger/hostility as well as overall aggression. Adverse effects were infrequent (Frankenburg and Zanarini 2002).

Potential Predictors of Positive Response to Valproate Versus Lithium

Mixed mania

Patients treated with divalproex who had mixed manic presentations had greater improvement in manic symptoms with divalproex than with lithium treatment in two randomized studies, one of which was placebo controlled (Bowden 1995; Freeman et al. 1992; Swann et al. 1997). Patients with mixed manic and pure manic symptoms who received divalproex had equivalent improvement, thereby indicating a lack of differential effectiveness of divalproex for the two subtypes (Swann et al. 1997). By contrast, during maintenance treatment, patients with mixed mania had equivalent responses to divalproex or lithium, with evidence of higher adverse effects as a function of illness features of mixed mania, compared with rates of adverse effects in patients with euphoric mania (Bowden et al. 2005). The results suggest that mixed manic states require more complex regimens than monotherapies for effective long-term management.

Mania with irritability

Results from a large randomized, double-blind study of manic patients showed that valproate was significantly superior to placebo in reducing symptoms of hostility, whereas lithium was not. Similarly, among patients with an irritable subtype of mania, divalproex reduced overall manic symptomatology, whereas lithium did not. By contrast, both valproate and lithium were effective in reducing impulsivity and hyperactivity (Swann et al. 2002). These results are consistent with studies of valproate for irritability in patients with personality disorders and for secondary manic states (Hollander et al. 2003; Kavoussi and Coccaro 1998; Noaghiul et al. 1998).

Irritability in manic patients has been associated with greater likelihood of response to divalproex than to lithium (Swann et al. 2002) and carbamazepine (Vasudev et al. 2000). Irritability has been the most consistently differentiating symptom favoring divalproex benefit in patients with disorders other than bipolar disorder—namely, Cluster B personality disorders (including borderline personality disorder) and schizophrenia (Casey et al. 2003; Frankenburg and Zanarini 2002; Hollander et al. 2003; Swann et al. 2002).

Prior nonresponse to lithium

Manic patients with a history of nonresponse to lithium who were randomly assigned to divalproex showed significantly greater improvement than patients who were randomized to lithium (Bowden et al. 1994). These data are consistent with reports of the efficacy of divalproex among patients selected for nonresponse to lithium (Pope et al. 1991).

High lifetime number of episodes

Divalproex was significantly more effective than lithium among manic patients with more than 10 episodes of illness (Swann et al. 1999) or more than 2 depressive episodes (Swann et al. 2000).

Rapid cycling

One blinded, randomized study reported that manic patients with a rapid-cycling illness course showed improvement in manic symptoms that was similar to the improvement seen in the entire patient cohort (Chamberlain et al. 1987).

In an open study of valproate in patients with rapid-cycling bipolar I or II disorder who were followed for a mean of 17.2 months, 52 of 58 (90%) had a marked or moderate antimanic response, 88 of 94 (94%) had a prophylactic antimanic response, 13 of 15 (87%) had an acute anti–mixed state response, and 17 of 18 (94%) had a prophylactic anti–mixed state response (Calabrese et al. 1993). A comparison of bipolar I rapid-cycling patients treated with divalproex, lithium, or the combination found that both drugs were highly effective acutely among patients entering into a manic episode but only moderately effective

among initially depressed patients (Calabrese et al. 2005). As discussed in the section on maintenance treatment, a longer-term maintenance study comparing divalproex and lithium reported low rates of response (both acute and sustained) for both treatments (Calabrese et al. 2005). Although reasons for the somewhat discrepant responses reported by the same group of investigators are not clear, in the aggregate the data suggest that rapid-cycling bipolar disorder is difficult to treat effectively with any monotherapy regimen.

In a double-blind, placebo-controlled trial of valproate in acutely manic bipolar patients, the 12 patients whose symptoms responded to valproate did not differ with respect to frequency of rapid cycling from the 5 valproate-treated patients who showed no response (McElroy et al. 1991).

Migraine in bipolar disorder

The prevalence of migraine is increased in persons with bipolar disorder, particularly bipolar II disorders. Valproate has been shown to be effective in the prophylaxis of migraine. The dosage of valproate is lower for migraine than for bipolar disorders, generally in the range of 500–1,000 mg/day (Freitag et al. 2002).

Other Potential Uses

Cotherapy in Schizophrenia

The use of valproate among patients with schizophrenia has increased, with one report indicating that over a third received valproate during hospitalization (Citrome et al. 2000; Wassef et al. 2000, 2001). A 4-week randomized, double-blind study of 242 schizophrenic patients who received risperidone or olanzapine alone, or divalproex plus the antipsychotic drug, indicated significantly greater improvement in Positive and Negative Syndrome Scale (PANSS)—Total and PANSS positive subscale scores among combination therapy patients from day 3 through day 21, but not at day 28. Platelet count was lower with combination therapy, and cholesterol levels increased with olanzapine or risperidone, compared with the significantly lower levels seen with antipsychotic plus divalproex. Weight gain did not differ between olanzapine and divalproex plus olanzapine; weight gain was greater with divalproex plus risperidone (7.5 pounds) than with risperidone (4.2 pounds) (Casey et al. 2003). A small (n = 12) randomized, blinded study also indicated greater global improvement and improvement in negative symptoms for patients who were receiving divalproex plus haloperidol than for those who were receiving haloperidol alone (Wassef et al. 2000). Divalproex appeared to be effective as adjunctive therapy for schizoaffective disorder in a retrospective study of 20 patients with schizoaffective disorder, bipolar type (Bogan et al. 2000).

Substance Use Disorders

Open-label studies have demonstrated the efficacy of valproic acid in reducing both cocaine craving and rates of relapse. The rate of relapse to cocaine in 55 patients treated with valproic acid was related to serum levels: patients who had serum levels of >50 µg/ml had lower rates of relapse as compared to those whose levels were <50 µg/ml. A direct relationship was also noted between serum levels and a decrease in number of days of cocaine use and improved levels of subjective functioning (Myrick et al. 2003).

Mania Secondary to Head Trauma or Organic Brain Syndromes

Evidence suggesting that secondary or complicated mania responds well to valproate is mixed. In an open study of 56 valproate-treated patients with mania, response was associated with the presence of nonparoxysmal abnormalities on the electroencephalogram but not with neurological soft signs or abnormalities on computed axial tomography scans of brain (McElroy et al. 1988). Nevertheless, there was a trend for responders to have histories of closed-head injury antedating the onset of their affective symptoms (Pope et al. 1988). Furthermore, case reports described successful valproate treatment of organic brain syndromes with affective features (Kahn et al. 1988) and mental retardation in patients with bipolar disorder or bipolar symptoms (Kastner et al. 1990; Sovner 1989).

Impulsive Aggression

Valproate has been reported to be effective in reducing impulsive aggression among patients with personality disorders. In the one randomized, placebo-controlled, double-blind study that has been reported, 249 patients with Cluster B personality disorders, intermittent explosive disorder, or posttraumatic stress disorder were treated for 12 weeks with divalproex or placebo. Divalproex did not differ from placebo among all subjects, but among the 96 Cluster B patients, aggression and irritability scores were improved significantly over the course of the study (Hollander et al. 2003). These results are consistent with smaller open trials of valproate for impulsive aggression (Kavoussi and Coccaro 1998).

SIDE EFFECTS AND TOXICOLOGY

Valproate has been extensively used over several decades; thus, its adverse-effect profile is well characterized (DeVane 2003; Prevey et al. 1996). Patients treated for epilepsy are more likely to experience adverse events than patients being treated for migraine or mania, consequent to generally higher doses of valproate and more complex drug regimens in epilepsy (DeVane 2003). In a large 1-year placebo-controlled study in bipolar disorder, tremor and reported weight gain were the only symptoms more commonly seen with divalproex than placebo (Prevey et al. 1996).

Gastrointestinal Effects

The most common gastrointestinal effects include nausea, vomiting, diarrhea, dyspepsia and anorexia. These are dose dependent, are usually encountered at the start of treatment, and are often transient (DeVane 2003). Immediate-release formulations of valproate are more likely to cause adverse events compared with the extended-release and enteric-coated formulations (Horn and Cunanan 2003; Zarate et al. 2000).

Tremor

Tremor consequent to valproate resembles benign essential tremor and is more frequently seen in patients with seizure disorder than in patients with bipolar disorder (DeVane 2003). Tremor may respond to a reduction in dosage or treatment with propranolol. Extended-release or enteric-coated formulations may lessen the frequency of tremor (Wilder et al. 1983; Zarate et al. 2000).

Sedation

Mild to moderate sedation is common, usually at the initiation of treatment. This adverse event is dose dependent and may be minimized by dosage reduction, slower titration, use of extended-release formulations, and taking all medication at bedtime.

Hair Loss

Loss of hair can occur with valproate, possibly consequent to chelation of trace metals by valproate in the intestines and to its effects on histone deacetylase, which result in interference with rapidly dividing cells. As with many other characteristic side effects, lowering dosage can control this effect in some patients. Valproate ingestion should be spaced several hours before or after ingestion of vitamin preparations, supplemental zinc, folate, and biotin, which appear able to reverse this adverse effect in some patients (Bowden 2003b; Hurd et al. 1984).

Pancreatitis

Valproate is associated with infrequent idiosyncratic acute pancreatitis. In three migraine trials, the rates of elevation of amylase were similar between the valproate and placebo groups (Pellock et al. 2002). Therefore, precautionary amylase levels provide little benefit in predicting pancreatitis. Psychiatrists should be guided by clinical symptoms of pancreatitis.

Hematological Effects

Leukopenia and thrombocytopenia are directly related to higher valproate serum level, usually ≥100 µg/mL (Acharya and Bussel 1996). Thrombocytopenia is usually mild and rarely associated with bleeding complications. Management consists of dosage reduction. Platelet counts below 75,000/mm (Casey et al. 2003) should also be regularly reassessed, since levels below this are more often associated with bruising or bleeding.

Hepatotoxicity

The risk of liver toxicity is largely limited to patients younger than 2 years of age, because hepatic function is immature until age 2. In long-term study of divalproex, full-dosage regimens for 1 year were associated with improvements in laboratory indices of hepatic function, and no hepatotoxicity was reported in the 187 patients treated with divalproex (Bowden et al. 2000). Similar results were reported in a 47-week study of divalproex in bipolar disorder (Tohen et al. 2003).

A risk factor for the development of hepatotoxicity is the concomitant administration of anticonvulsants such as carbamazepine, which cause induction of enzymes involved in the metabolism of valproate, leading to increased concentrations of an active and hepatotoxic metabolite, 2-propyl-4-pentenoic acid.

Weight Gain

Weight gain ranging from 3–24 pounds is seen in 3%–20% of patients treated with valproic acid over a time course that has ranged from 3 to 12 months (Bowden 2003b). In a 47-week study, divalproex (dosage range = 500–2,500 mg/day) resulted in less weight gain in manic and mixed-manic patients than olanzapine (1.22 kg vs. 2.79 kg) (Tohen et al. 2003). In a 3-week trial in manic patients, weight gain as a side effect was seen in 10% of valproate-treated patients and in 25% of olanzapine-treated patients (Zajecka et al. 2002). Valproate serum levels greater than 125 µg/mL are more likely to cause weight gain than those below this level (Bowden et al. 2000). If increased appetite and weight gain occur, valproate dosage should be lowered so long as clinical effectiveness is maintained, or alternatively should be discontinued and replaced by regimens without risks of weight gain.

Cognitive Dulling

Valproate has infrequent adverse effects on cognitive functioning, and it improves cognition in some patients (Prevey et al. 1996). In a 20-week randomized, observer-blinded, parallel-group trial, the addition of valproate to carbamazepine resulted in improvement on short-term verbal memory (Aldenkamp et al. 2000). No adverse cognitive effects with the use of valproate were seen in a group of elderly patients (mean age = 77 years) (Craig and Tallis 1994).

Lipid-Lowering Effects

Several studies indicate that valproate reduces total cholesterol and low-density lipoprotein (LDL) and high-density lipoprotein (HDL) cholesterol levels and protects against the adverse effects of some antipsychotic drugs on lipid function. An open case series found no changes in lipid profiles in children receiving long-term valproate (Geda et al. 2002). Valproate significantly

lowered total and LDL cholesterol in comparison with phenobarbital and carbamazepine in a study of children with epilepsy (Ylmaz et al. 2001). In a 47-week study in manic and mixed-manic patients, valproate reduced cholesterol levels (Tohen et al. 1995). In patients with schizophrenia, valproate adjunctive to olanzapine or risperidone resulted in lowered cholesterol levels (Casey et al. 2003). The cholesterol-lowering effect of valproate is apparent even in short 3-week trials in acute mania. For the full sample in the randomized, blinded study, total cholesterol decreased significantly more in the divalproex group than in the placebo group (−13.47 mg/dL vs. −2.46 mg/dL; $P = 0.001$). Stratification by baseline total cholesterol levels (≥200 mg/dL vs. <200 mg/dL) indicated that reduction with divalproex compared with placebo was limited to the stratum with higher mean baseline values (−18.6mg/dL vs. −6.5 mg/dL, respectively) (Bowden et al. 2006). In a 12-week comparison of divalproex and olanzapine in bipolar disorder patients, cholesterol and LDL levels fell with valproate use, compared with significant increases in olanzapine-treated patients (Zajecka and Weisler 2000).

Polycystic Ovarian Syndrome

Polycystic ovarian syndrome (PCOS) occurs in 4%–12% of women and is the leading cause of ovulatory infertility. PCOS appears to have a higher incidence in women with epilepsy; PCOS was found in 20% of 50 women with temporal lobe epilepsy and in 25% of 20 women with complex partial seizures, most of whom were unmedicated (Ernst and Goldberg 2002).

The prevalence of menstrual disturbances is high in women with bipolar disorder, irrespective of medication received, probably representing a dysfunction of the hypothalamic-pituitary-gonadal axis. A study of 10 lithium-treated, 10 valproate-treated, and 2 carbamazepine-treated women with bipolar disorder found a high frequency of menstrual dysfunction in all groups. Ultrasound identified an increased number of ovarian follicles in 1 of the lithium-treated patients but no increases in any valproate-treated patient. PCOS did not occur in any of the patients. Hormonal assessment of estrone, luteinizing hormone, follicle-stimulating hormone, testosterone, and dehydroepiandrosterone (DHEA) yielded no abnormal values in any patient (Rasgon et al. 2000).

In the cross-sectional National Institute of Mental Health Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) program, new-onset menstrual cycle irregularities and hyperandrogenism occurred in 10.5% of 86 women treated with valproate as a component of their prior treatment regimen before entering the STEP-BD study (Joffe et al. 2006a). A follow-up study of 7 women who had developed valproate-associated PCOS reported that PCOS reproductive features remitted in 3 of the 4 patients who discontinued valproate and persisted in all 3 patients who remained on valproate (Joffe et al. 2006b). No changes in polycystic ovarian morphology were associated with valproate in either study.

A study evaluating four groups of women with epilepsy—an untreated group, a carbamazepine-treated group, a valproate-treated group, and a group receiving more than one antiepileptic agent—found no differences in rates of PCOS among the drug-treated groups (Bauer et al. 2000). Valproate did not alter endocrine measures indicative of PCOS in a 12- to 15-month study in rhesus monkeys (Ferin et al. 2003). Obesity may be a mechanistic pathway whereby valproate (and potentially other drugs) predisposes women to PCOS. It is advisable to treat weight gain as a risk factor for possible development of PCOS and intervene as needed to avoid clinically significant weight gain.

Use During Pregnancy and Lactation

Birth Defects

Valproate is associated with an increased incidence of birth defects, including neural tube defects, craniofacial anomalies, limb abnormalities, and cardiovascular anomalies, if infants are exposed to valproic acid in the first 10 weeks of gestation (Kinrys et al. 2003; Samren et al. 1997). Neural tube defects, the most serious of the congenital anomalies, occur in 1%–4% of such infants. Prenatal exposure to valproate prior to the closure of the neural tube, during the fourth of week of gestation, leads to a prevalence of spina bifida in 1%–2% of infants, a 10–20 times greater rate than in the general population (Kinrys et al. 2003). Most of the available data involved patients with epilepsy, who are generally treated with higher doses of valproate than the doses employed for bipolar disorder and migraine and who are often concurrently treated with other teratogenic anticonvulsants (Bowden 2003b). The risk of malformations is increased with higher dosages and higher serum levels of valproate, as well as with concomitant use of other anticonvulsants (due to higher concentration of 2-propyl-4-pentenoic acid, a teratogenic agent); is possibly decreased with supplemental folic acid; and is definitely reduced with lower dosages of valproate (Bowden 2003b). Because alternate treatment strategies lacking teratogenic risk may work to effectively manage bipolar symptoms, valproate should generally be discontinued if conception is desired and during the early course of pregnancy if it occurs.

Breast-Feeding

Valproate is minimally present in breast milk. Piontek et al. (2000) reported that among six mother–infant pairs, serum valproate levels in the infants ranged from 0.9% to 2.3% of the mother's serum level, with absolute serum levels of 0.7–1.56 µg/mL. The valproate concentration in an infant was 1.5% of the maternal concentration (Wisner and Perel 1998).

Overdose

Regarding overdose, recovery from coma has occurred with serum valproate concentrations of greater than 2,000 µg/mL. In addition, serum valproate concentrations have been reduced by hemodialysis and hemoperfusion, and valproate-induced coma has been reversed with naloxone (Rimmer and Richens 1985). It is generally not necessary to perform routine blood monitoring

of hematological and hepatic function in patients receiving valproate (Willmore et al. 1991). Superior to routine laboratory screening is educating the patient about the signs and symptoms of organ system dysfunction and instructing the patient to report these symptoms if they occur, in conjunction with careful monitoring of the patient's clinical status.

DRUG–DRUG INTERACTIONS

Because valproate is highly protein bound and extensively metabolized by the liver, a number of potential drug–drug interactions may occur with other protein-bound or metabolized drugs (Fogel 1988; Levy et al. 2002; Rall and Schleifer 1985; Rimmer and Richens 1985). Thus, free fraction concentrations of valproate in serum can be increased and valproate toxicity can be precipitated by coadministration of other highly protein-bound drugs (e.g., aspirin) that can displace valproate from its protein-binding sites.

Because valproate tends to inhibit drug oxidation—it is the only major antiepileptic that does not induce hepatic microsomal enzymes—serum concentrations of a number of metabolized drugs can be increased by the coadministration of valproate. Valproate has been reported to increase serum concentrations of phenobarbital, phenytoin, and tricyclic antidepressants. Conversely, the metabolism of valproate can be increased, and valproate serum concentrations subsequently decreased, by coadministration of microsomal enzyme–inducing drugs such as carbamazepine. Drugs that inhibit metabolism may increase valproate concentrations in serum. Fluoxetine, for instance, has been reported to boost valproate concentrations (Sovner and Davis 1991).

The competitive inhibition by valproate of excretion of lamotrigine via glucuronidation requires that lamotrigine be started at a lower dosage, usually 25 mg every other day, and increased more cautiously. Steady-state dosage of lamotrigine used with valproate is also generally lower, but not in all patients.

CONCLUSION

The broad spectrum of efficacy in bipolar spectrum disorders and generally good tolerability of valproate make it a foundation of treatment for many patients with bipolar disorders. For optimal results, most patients should be treated with a formulation that permits single daily dosing and has the lowest peak-to-trough serum level, which in the United States currently is extended-release divalproex. Although onset of action of valproate is prompt with loading-dose strategies, given the paramount importance of tolerability and adherence of bipolar patients to long-term treatment regimens, gradual dosage increase is preferable for all but severely manic states.

During maintenance treatment, it is often important to reduce dosage if adverse effects persist. Valproate alleviates and is prophylactic principally for manic symptoms, although prophylactic benefits for depression are now relatively well established. A history of many episodes or current irritability may be a particularly strong indicator of a favorable response to valproate. Although some patients may have acute and sustained remission with valproate monotherapy, many patients are more effectively treated with combinations, including other mood stabilizers and adjunctive medications. All current medications with established or putative roles can be combined with valproate.

Although valproate is now approved for mania in most countries, well-designed studies that advance clinical knowledge continue to be conducted with this drug. Additionally, scientific information coming from studies in patients with migraine, epilepsy, and other psychiatric disorders will continue to provide useful, reliable information, especially regarding prescribing practices and adverse-effect profiles and management.

Chapter 37. Carbamazepine and Oxcarbazepine

CARBAMAZEPINE AND OXCARBAZEPINE: INTRODUCTION

Pharmacotherapy of bipolar disorder is a complex and rapidly evolving field. The development of new treatments has helped to refine concepts of illness subtypes and generated important new management options. Although the mood stabilizers—the first-line agents lithium, valproate, and lamotrigine and the alternative agents carbamazepine (CBZ) and oxcarbazepine (OXC)—are considered the primary medications for bipolar disorder, antipsychotics, antidepressants, anxiolytics, and a new generation of anticonvulsants are commonly combined with mood stabilizers in clinical settings (American Psychiatric Association 2002; Ketter 2005; Suppes et al. 2005). These diverse medications have varying pharmacodynamics, pharmacokinetics, drug–drug interactions, and adverse effects, thus offering not only new therapeutic opportunities but also a variety of new potential pitfalls.

Therefore, clinicians are challenged with integrating complex data regarding efficacy and adverse-effect spectra with pharmacological properties in their efforts to provide safe, effective state-of-the-art pharmacotherapy for patients with bipolar disorder. In this chapter, we review the preclinical and clinical pharmacology of CBZ and its analog OXC. In the past, CBZ was considered an alternative to lithium and valproate rather than a first-line intervention in the treatment of bipolar disorder (American Psychiatric Association 2002) in view of methodological limitations of early studies of efficacy in bipolar disorder, complexity of use because of adverse effects and drug–drug interactions, and lack of U.S. Food and Drug Administration (FDA) indication for the treatment of bipolar disorder. However, evidence of the efficacy of a proprietary CBZ extended-release formulation (Equetro) in two randomized, double-blind, placebo-controlled, parallel-group studies in bipolar disorder patients with acute manic and mixed episodes (Weisler et al. 2004, 2005) has addressed methodological concerns and led to CBZ's receiving an indication for the treatment of acute manic and mixed episodes in patients with bipolar disorder. Importantly, in selected patients, CBZ and OXC may offer efficacy and tolerability that are favorable compared with first-line therapies and thus can be important treatment options for some individuals with bipolar disorders. In particular, CBZ's low propensity to cause the weight gain and metabolic problems seen with some other agents may lead clinicians to reassess its role in the management of patients with bipolar disorder (Ketter et al. 2005). Although OXC appears easier to use than CBZ, use of OXC remains limited by the lack of compelling data regarding its efficacy in bipolar disorder.

HISTORY AND DISCOVERY

CBZ, as one of the initial alternatives to lithium and older antipsychotics, has played an important role in the development of therapeutic interventions for bipolar disorder (Post et al. 2007). Lithium was reported by Cade (1949) to be effective in acute mania and saw widespread use in Europe by the 1960s, but in view of safety concerns (risk of toxicity), it was only approved for the treatment of acute mania in the United States in 1970. CBZ was developed in 1957 by J. R. Geigy AG in Europe, and its efficacy in epilepsy and paroxysmal pain was appreciated by the 1960s and in bipolar disorder by the early 1970s (Takezaki and Hanaoka 1971). As with lithium, marketing of CBZ in the United States was delayed because of safety concerns (risk of blood dyscrasias), and CBZ was thus not approved for the treatment of epilepsy in adults until 1974, in children older than 6 years until 1978, and without age limitation until 1987.

The first-generation antipsychotic chlorpromazine was approved for the treatment of acute mania in the United States in 1973. The next year, lithium received a maintenance indication for the treatment of bipolar disorder. Thus, in the 1970s, acute mania was managed primarily with lithium and first-generation antipsychotics. Lithium proved dramatically effective in classic euphoric mania but had limitations, which included the need for initial titration and a clinically significant response latency. In addition, lithium proved less effective in patients with mixed or dysphoric mania, rapid cycling, greater numbers of previous episodes, mood-incongruent delusions, or concurrent substance abuse than in those with classic bipolar disorder (Ketter and Wang 2002). The response latency and the spectrum of efficacy limitations of lithium resulted in the common practice of concurrently administering first-generation antipsychotics in acute mania. However, first-generation antipsychotics had adverse effects that imposed substantial limitations, as mood disorder patients appeared to be at even greater risk than

schizophrenia patients for acute extrapyramidal side effects (Nasrallah et al. 1988) and tardive dyskinesia (Kane and Smith 1982). In addition, these agents appeared to have unimodal (antimanic but not antidepressant) activity in bipolar disorder in that they could exacerbate the depressive component of the illness (Ahlfors et al. 1981).

These limitations of lithium and first-generation antipsychotics led investigators to explore other treatment options for bipolar disorder. On the basis of early reports of favorable psychotropic profiles in epilepsy patients and preliminary observations in mood disorders, systematic investigations of CBZ (Ballenger and Post 1978) and valproate commenced, and these anticonvulsants emerged as effective in acute mania, even in subtypes associated with lithium resistance. Thus, CBZ and then valproate were increasingly used off label for bipolar disorder in the 1980s and early 1990s, respectively. The CBZ analog OXC was anecdotally reported as useful in bipolar disorder in the 1980s (Müller and Stoll 1984) but was not marketed in the United States for the treatment of epilepsy until 2000.

Because of economic concerns such as patent protection limitations and the high cost of obtaining FDA approval, a CBZ indication for bipolar disorder was not initially sought in the United States but was obtained from agencies in Canada, Japan, Australia, and several European countries. The development of divalproex, a well-tolerated proprietary valproate formulation, allowed the patent protection necessary to make seeking an FDA indication for bipolar disorder economically feasible. The FDA's approval of divalproex for the treatment of acute mania in 1994, lack of major safety concerns, and relative ease of use were important factors in divalproex use overtaking that of CBZ and even lithium by the late 1990s. In addition, divalproex's efficacy in acute mania was considered better established than that of CBZ, because the pivotal trials for obtaining the divalproex mania indication were conducted with contemporary randomized, parallel, double-blind, placebo-controlled paradigms (Bowden et al. 1994; Pope et al. 1991), whereas early controlled CBZ studies in bipolar disorder used alternative (e.g., active comparator and on–off–on) designs, as described later in this chapter (see section "Indications and Efficacy"). Despite the limitations in the controlled maintenance data for both drugs, CBZ and divalproex were considered mood stabilizers along with lithium.

The emergence of and evidence of the efficacy of a proprietary CBZ extended-release formulation (Equetro) in two randomized, double-blind, placebo-controlled studies in patients with acute manic and mixed episodes (Weisler et al. 2004, 2005) led to an FDA indication in late 2004 for this CBZ formulation in the treatment of acute manic and mixed episodes in patients with bipolar disorder.

OXC was approved for the treatment of epilepsy in the United States in 2000, in the setting of the development of several new anticonvulsants in the 1990s. The new anticonvulsants appear to have heterogeneous psychotropic profiles (Ketter et al. 2003), with only OXC thus far showing benefit in some controlled (albeit small) trials in acute mania (Emrich 1990) and lamotrigine in the prophylaxis of and (to a lesser extent) acute treatment of bipolar depression. As with CBZ, economic concerns such as patent protection limitations and the high cost of obtaining FDA approval are substantial barriers to seeking an OXC indication for acute mania in the United States. Because of its greater ease of use, OXC is considered by some to be an important alternative to CBZ (American Psychiatric Association 2002). However, use of OXC remains limited by the lack of compelling data regarding its efficacy in bipolar disorder.

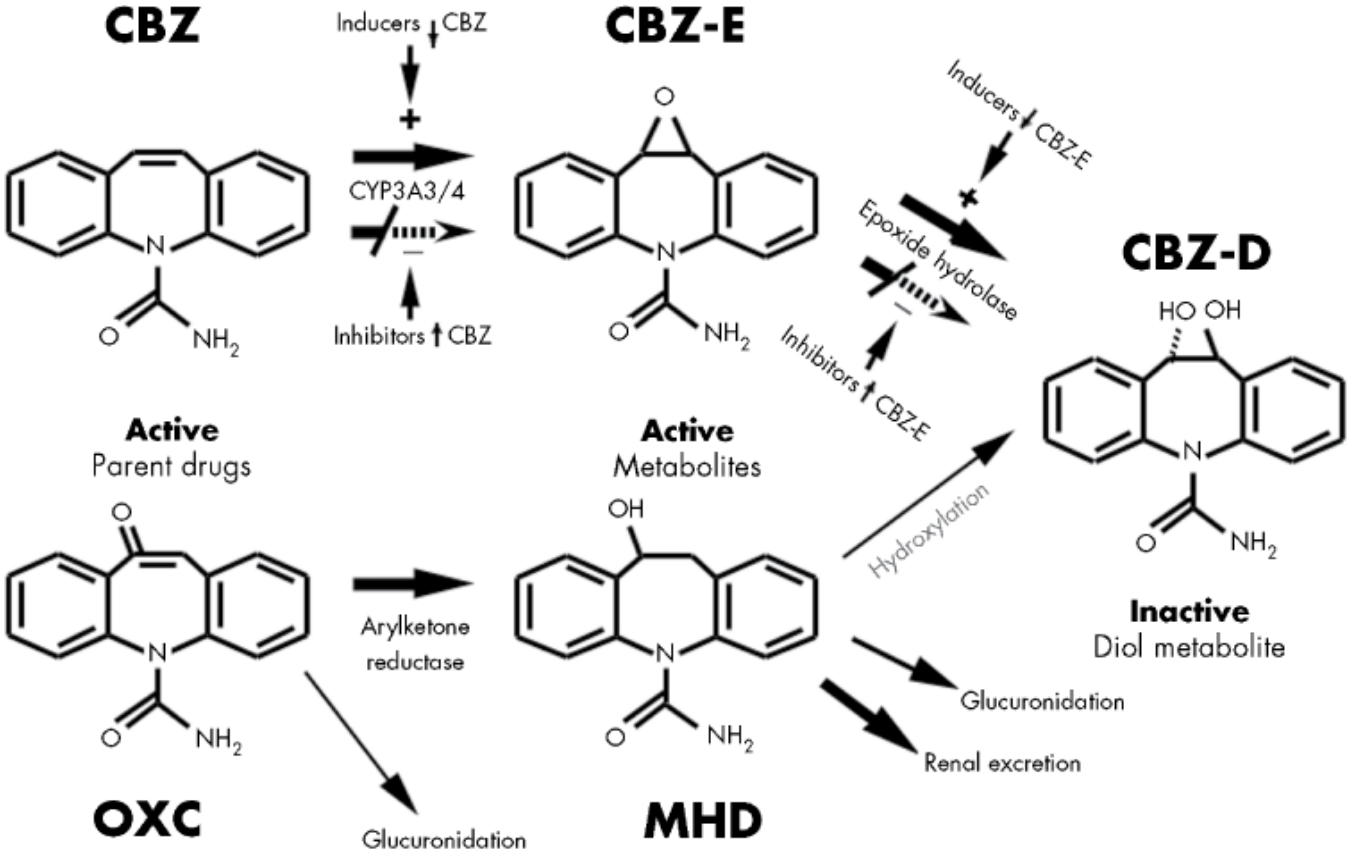
STRUCTURE–ACTIVITY RELATIONS

CBZ is an iminostilbine derivative with a dibenzazepine nucleus. CBZ's tricyclic nucleus appears to relate more to local anesthetic and antihistaminic actions than to anticonvulsant actions. In contrast, the carbamyl (carboxamide) group at position 5 appears related to substantial anticonvulsant effects. CBZ's 5-carboxamide substituent, in contrast to the 5-aryl substituent of imipramine, appears to account for CBZ's markedly different effects compared with those of imipramine, as described below. OXC differs structurally from CBZ only in that it has a ketone substitution at the 10,11-position, and as noted below, the bulk of the evidence thus far suggests that this structural similarity is paralleled by a mechanistic similarity.

PHARMACOLOGICAL PROFILE

CBZ and OXC have a preclinical anticonvulsant profile similar to that of phenytoin and less broad than that of valproate or lamotrigine. Thus, CBZ and OXC, like phenytoin, valproate, and lamotrigine, are effective in the maximal electroshock model of generalized tonic and/or clonic seizures, and like phenytoin but unlike valproate and lamotrigine, they are not effective in the pentylenetetrazole model of absence seizures. CBZ and OXC, like phenytoin, valproate, and lamotrigine, are effective in blocking seizures resulting from amygdala kindling (a model of partial seizures). However, CBZ and OXC, like phenytoin and lamotrigine but unlike valproate, fail to block kindling development (a model of epileptogenesis).

As expected from their preclinical profiles, CBZ and OXC, like phenytoin, valproate, and lamotrigine, are effective in partial seizures with and without secondary generalization, and like phenytoin but unlike valproate and lamotrigine, they are ineffective in absence seizures. CBZ and OXC also have analgesic effects and thus are effective in trigeminal neuralgia.



PHARMACOKINETICS AND DISPOSITION

Carbamazepine

CBZ is available in the United States as a proprietary product (Tegretol) marketed for epilepsy by Novartis Pharmaceuticals Corporation in suspension (100 mg/5 mL), chewable tablets (100 mg), nonchewable tablets (200 mg), and extended-release (Tegretol XR) tablets (100-, 200-, and 400-mg) ("Tegretol" 2008). An additional proprietary extended-release formulation marketed for epilepsy as Carbatrol (by Shire US Inc.) and for bipolar disorder as Equetro (by Validus Pharmaceuticals) is available in 100-, 200-, and 300-mg capsules ("Carbatrol" 2008; "Equetro" 2008). Intramuscular and depot formulations are not available. CBZ is also available in generic formulations. Differences have been observed in the bioavailability of proprietary and generic formulations (Meyer et al. 1992).

CBZ is extensively metabolized, with only about 3% excreted unchanged in the urine. The main metabolic pathway of CBZ (to its active 10,11-epoxide, CBZ-E) appears to be mediated primarily by cytochrome P450 (CYP) 3A3/4 (Figure 37–1, top), with a minor contribution by CYP2C8 (Kerr et al. 1994). This epoxide pathway accounts for about 40% of CBZ disposition and an even greater proportion in patients with induced epoxide pathway metabolism (presumably via CYP3A3/4 induction) (Faigle and Feldmann 1995). Although a genetic polymorphism has been observed for CYP2C8 (Wrighton and Stevens 1992), this probably does *not* account for the variability observed in CBZ disposition, in view of the minor role of this isoform. The frequency distribution of CBZ kinetic parameters is unimodal, consistent with CYP3A3/4 (which lacks genetic polymorphism) being the crucial isoform. With enzyme induction (of the epoxide pathway, presumably via CYP3A3/4 induction), formation of CBZ-E triples, its subsequent transformation to the inactive diol (CBZ-D) doubles, and thus the ratio of CBZ-E to CBZ increases (Eichelbaum et al. 1985). Other pathways include aromatic hydroxylation (25%), which is apparently mediated by CYP1A2 and not induced concurrently with the epoxide pathway, and glucuronide conjugation of the carbamoyl side chain (15%) by uridine diphosphoglucuronosyltransferase (UGT), presumably primarily by UGT2B7 (Staines et al. 2004). These other pathways yield inactive metabolites.

CBZ has erratic absorption and a bioavailability of about 80%. CBZ should not be exposed to humidity, because this can cause solidification and decrease bioavailability (Nightingale 1990). It is about 75% bound to plasma proteins and has a moderate volume of distribution (about 1 L/kg). Before autoinduction of the epoxide pathway, the half-life of CBZ is about 24 hours, and the clearance is about 25 mL/minute. However, after autoinduction (2–4 weeks into therapy), the half-life falls to about 8 hours, and clearance rises to about 75 mL/minute. This may require dosage adjustment to maintain adequate blood concentrations and therapeutic effects. The active CBZ-E metabolite has a half-life of about 6 hours and is converted to an inactive diol (CBZ-D) by epoxide hydrolase. The extended-release CBZ formulations available in the United States given twice a day yield steady-state CBZ concentrations similar to those seen with the immediate-release formulation given four times a day (Garnett et al. 1998; Thakker et al. 1992).

In the treatment of acute mania, two divergent clinical needs influence the rate of dosage titration. First, there is a pressing need for rapid control of the manic syndrome, which suggests that faster titration to higher doses could provide more rapid attainment of sufficient serum concentrations, potentially yielding quicker onset not only of nonspecific sedation but also of specific antimanic effects. On the other hand, there is a need to not excessively burden patients with the increased adverse effects associated with overly rapid escalation of CBZ dosage. Such adverse effects include neurotoxicity (sedation, diplopia, and ataxia) and gastrointestinal disturbances that not only can complicate acute management but also may lead patients to develop negative perceptions about the adverse effects of CBZ that later interfere with their adherence to prophylactic therapy. Thus, although a loading-dose strategy may be tolerated and effective in the treatment of mania with valproate (Keck et al. 1993), the potential for neurotoxic adverse effects limits such an approach with CBZ.

Nonetheless, in the inpatient therapy of mania, CBZ is commonly started at 400–800 mg/day in divided doses, with the dosage increased as tolerated (by 200 mg/day every 1–4 days) to provide clinical efficacy. In recent controlled

studies, a beaded extended-release capsule formulation was started at 200 mg twice per day and titrated by daily increments of 200 mg to final dosages as high as 1,600 mg/day (Weisler et al. 2004, 2005). Titration of dosage against adverse effects is more important than blood concentrations, which usually reach between 4 and 12 μg/mL (17 and 51 μM/L), and there does not appear to be a close blood concentration–efficacy relationship for CBZ in treating either seizure or mood disorders. Usual dosages are 800–1,600 mg/day given in up to three or four divided doses with the immediate-release formulation. Extended-release formulations permit two divided doses per day, and most mood disorder patients may even be able to take the entire daily dose at bedtime. Although this strategy is convenient, it may not be feasible in some individuals because of neurotoxicity at peak serum concentrations, which occurs about 4–8 hours after ingesting CBZ. CBZ has fairly rapid onset of antimanic efficacy, in some comparisons similar to that of neuroleptics. Thus, lack of clinical improvement after 7–10 days may be an indication that augmentation or alternative strategies should be considered.

In a recent report of open extension therapy after controlled acute mania studies, beaded extended-release capsule CBZ was started at 200 mg twice per day and titrated by increments of 200 mg every 3 days (versus every day in the acute studies) to final dosages as high as 1,600 mg/day (Ketter et al. 2004). This approach decreased the incidence of central nervous system (dizziness, somnolence, ataxia), digestive (nausea, vomiting), and dermatological (pruritus) adverse effects by about 50%. Euthymic or depressed patients tend to tolerate aggressive initiation less well than do manic patients. Thus, in less acute situations such as the initiation of prophylaxis or adjunctive use, CBZ is often started at 100–200 mg/day and increased (as necessary and tolerated) by 200 mg/day every 4–7 days. Even this gradual initiation may result in adverse effects. Thus, starting with 50 mg (half of a chewable 100-mg tablet) at bedtime and increasing the dosage by 50 mg every 4 days may provide better tolerability. Moreover, doses of CBZ initially associated with adverse effects during the first 2 weeks of therapy may be readily used after 1 month of therapy, once autoinduction of CBZ metabolism has decreased serum CBZ concentrations (Cereghino 1975) and accommodation and tolerance to adverse effects such as sedation have occurred. Target dosages are commonly between 600 and 1,200 mg/day, yielding serum levels from 4 to 12 μg/mL, with the higher portion of the range used acutely, and lower doses used in prophylaxis or adjunctive therapy. In a CBZ versus lithium maintenance study, serum trough CBZ concentrations were maintained at 4–12 μg/mL, with a mean of 6.4 μg/mL (Greil et al. 1997). In another CBZ versus lithium maintenance study, serum trough CBZ concentrations were maintained at 4 to 12 μg/mL, with a mean of 7.7 μg/mL (Denicoff et al. 1997).

Because CBZ dosage and serum and cerebrospinal fluid concentrations fail to correlate with psychotropic efficacy (Post 1989; Post et al. 1983a, 1984a), it is common practice to gradually increase CBZ dosage as tolerated, monitoring both adverse effects and clinical efficacy, until therapeutic efficacy is adequate, adverse effects supervene, or serum concentrations exceed 12 μg/mL. The 4- to 12-μg/mL serum CBZ concentration range from use in epilepsy may be considered as a broad target, and CBZ serum concentrations may be used as checks for pharmacokinetic problems. The active CBZ-E metabolite can yield therapeutic and adverse effects similar to those of CBZ but is not detected in conventional CBZ assays. Thus, the unwary clinician may misinterpret the significance of therapeutic or adverse effects associated with low or moderate serum CBZ concentrations.

Cerebrospinal fluid CBZ-E (but not CBZ) concentrations may correlate with degree of clinical improvement in patients with mood disorders (Post et al. 1983a, 1984a, 1984c). Clinical improvement in depressed patients may tend to correlate with serum CBZ-E (but not CBZ) concentration and serum CBZ-E to CBZ ratio. This ratio may suggest a possible relationship between clinical response and the degree of enzyme induction.

In responders, a dose–response relationship may be evident, so that slowly increasing CBZ doses to maximize response in the absence of significant adverse effects is a clinically useful strategy. However, if there is no hint of therapeutic response at moderate doses, it is unlikely that pushing to very high doses will be beneficial.

Oxcarbazepine

OXC is available in the United States as a proprietary product (Trileptal) manufactured by Novartis Pharmaceuticals Corporation in a 300-mg/5-mL suspension and in 150-, 300-, and 600-mg tablets ("Trileptal" 2008). Extended-release, intramuscular, and depot formulations are not available.

OXC is 96% absorbed, and the modest effect of food on OXC kinetics does not appear to be of therapeutic consequence (Degen et al. 1994). OXC is 60% bound to plasma proteins. Like CBZ, OXC has complex metabolism (see Figure 37–1, bottom). Thus, OXC is rapidly reduced to an active monohydroxy derivative (MHD) by cytosol arylketone reductase. The MHD is 40% bound to plasma proteins, has a moderate volume of distribution (about 0.8 L/kg), and has a half-life of about 9 hours. OXC is eliminated primarily in the form of MHD (70%) and MHD glucuronide conjugates (20%), with small portions (10%) in the form of OXC glucuronide conjugates and CBZ-D.

OXC does not cause autoinduction and yields substantially less heteroinduction than does CBZ. Thus, as described below, drug–drug interactions are less problematic with OXC than with CBZ (Baruzzi et al. 1994).

In epilepsy patients, OXC is commonly started at 600 mg/day and increased weekly by 600 mg/day, with final dosages commonly ranging between 900 and 2,400 mg/day in two divided doses, yielding serum concentrations of approximately 13–35 μg/mL (50–140 μM/L) (Johannessen et al. 2003; "Trileptal" 2008). In bipolar disorder patients, OXC, like CBZ, is titrated to clinical desired effect as tolerated, with the serum concentration range used in epilepsy considered as a broad target and with OXC serum concentrations used as checks for pharmacokinetic problems. For patients taking CBZ, equipotent doses of OXC range from 1.2 to 1.5 times the CBZ dose. In an early small, double-blind, on–off–on acute mania trial, the mean OXC dose was 1,886 mg/day (range 1,800–2,100) (Emrich et al. 1983). In small active-comparator multicenter studies in acute mania, mean OXC dosages were 2,400 mg/day and 1,400 mg/day in comparison with haloperidol and lithium, respectively (Emrich 1990). In a recent pediatric acute mania study, OXC was increased every 2 days by 300 mg/day to a maximum of 900–2,400 mg/day, with mean dosages of 1,200 mg/day and 2,040 mg/day in children and adolescents, respectively, but therapeutic effects did not exceed that of placebo (Wagner et al. 2006).

MECHANISMS OF ACTION

CBZ and OXC have not only structural but also mechanistic similarities. However, these agents have such a diversity of biochemical effects that linking these mechanisms to their varying clinical actions presents a considerable challenge.

Carbamazepine

As noted above, although CBZ has a tricyclic structure like imipramine's, the two agents have markedly different neurochemical, hepatic, and clinical effects. Thus, CBZ, unlike imipramine, lacks major effects on monoamine reuptake or high affinity for histaminergic or cholinergic receptors and, unlike many antidepressants, fails to downregulate β-adrenergic receptors. Also, CBZ, unlike antipsychotics, does not block dopamine receptors. However, CBZ has a wide range of other cellular and intracellular effects, as described below.

One way to consider CBZ's diverse actions is from the perspective of commonalities with and dissociations from the actions of the other mood stabilizers, lithium and valproate. CBZ shares a few mechanistic commonalities with both of these mood stabilizers in that all three agents increase limbic γ-aminobutyric acid type B ($GABA_B$) receptors, decrease GABA and dopamine turnover, inhibit inositol transport, and weakly inhibit calcium influx by an *N*-methyl-D-aspartate (NMDA)–mediated effect in preclinical studies. Chronic (but not acute) lithium, CBZ, and valproate increase hippocampal (but not frontal, thalamic, or striatal) $GABA_B$ (but not $GABA_A$) receptors in rats (Motohashi 1992; Motohashi et al. 1989) and decrease GABA turnover in rodents (Bernasconi 1982; Bernasconi and Martin 1979; Bernasconi et al. 1984), suggesting that hippocampal $GABA_B$ receptor mechanisms and decreased GABA turnover could be important in medications that stabilize mood.

However, CBZ shares some actions with valproate but not lithium, and shares other actions with lithium but not valproate. Thus, CBZ, like valproate but unlike lithium, decreases glutamate and aspartate release by blocking sodium channels, decreases somatostatin-like immunoreactivity, and increases potassium efflux and serum L-tryptophan. CBZ, like lithium but unlike valproate, decreases serum levothyroxine, cyclic adenosine monophosphate (cAMP), and cyclic guanosine monophosphate (cGMP) and increases serotonin and substance P neurotransmission. CBZ differs from both lithium and valproate in that it has effects at peripheral-type benzodiazepine receptors, blocks adenosine A_1 receptors, increases G protein–stimulating alpha subunits ($G_s\alpha$) and inositol monophosphatase (IMPase), and decreases G protein–inhibitory alpha subunits ($G_i\alpha$).

In contrast, CBZ may lack certain intracellular actions shared by valproate and lithium, such as increasing expression of the cytoprotective protein bcl-2 and transcription factor AP-1 binding and decreasing glycogen synthase kinase-3 beta (GSK-3β), protein kinase C (PKC), and myristoylated alanine-rich C kinase substrate (MARCKS). CBZ appears to lack additional intracellular signaling actions seen with lithium but not valproate, such as decreasing G protein coupling to phosphatidylinositol (PI) and adenylate cyclase, phospholipase C, and inositol and increasing intracellular calcium, as well as increasing basal and decreasing stimulated cAMP. CBZ also lacks other actions seen with lithium but not valproate, such as having effects on neuropeptide Y or glucocorticoid type II receptors or decreasing calcium influx or α_2-adrenergic neurotransmission. CBZ appears to lack some actions seen with valproate but not lithium, such as increasing microtubule-associated protein (MAP) kinase, decreasing GABA catabolism, and increasing GABA release.

In one three-way mechanistic dissociation, lithium decreased, CBZ increased, and valproate did not change IMPase

(Vadnal and Parthasarathy 1995). CBZ's mixture of mechanistic commonalities with and dissociations from lithium and valproate is consistent with the view that CBZ's clinical effects in bipolar disorder may overlap with but are not identical to those of lithium and valproate.

Another potentially useful way of considering CBZ's diverse mechanisms is from the perspective of onset of action (Post 1988). Thus, CBZ cellular actions with acute onset that might parallel the time course of clinical anticonvulsant effects include decreasing sodium influx and glutamate release, increasing potassium conductance, and acting on peripheral benzodiazepine and α_2-adrenergic receptors. Acute $GABA_B$ receptor actions like those of baclofen may relate to the rapid onset of clinical analgesic effects. Acute or subchronic actions such as increasing striatal cholinergic neurotransmission; decreasing adenylate cyclase activity stimulated by dopamine, norepinephrine and serotonin; and decreasing turnover of dopamine, norepinephrine, and GABA may be pertinent to clinical antimanic effects. Finally, actions requiring chronic administration may be most closely related to clinical antidepressant effects. These include increasing serum and urinary free cortisol, free tryptophan, substance P sensitivity, and adenosine A_1 receptors and decreasing cerebrospinal somatostatin-like immunoreactivity.

Oxcarbazepine

Less is known about OXC mechanisms than about CBZ mechanisms. The bulk of the evidence thus far suggests that OXC's structural similarity to CBZ is paralleled by mechanistic similarity (Ambrosio et al. 2002). For example, OXC, like CBZ, appears to decrease sodium (Benes et al. 1999; Wamil et al. 1994) and calcium (Stefani et al. 1995) influx, glutamate release (Ambrosio et al. 2001), and serum thyroxine (T_4) concentrations (Isojarvi et al. 2001b); increase potassium conductance (McLean et al. 1994) and dopaminergic neurotransmission (Joca et al. 2000); and block adenosine A_1 receptors (Deckert et al. 1993). However, there may be some mechanistic dissociations, particularly given OXC's and CBZ's marked differences in degree of hepatic enzyme induction. For example, OXC appears to be a less potent modulator of voltage-gated calcium channels compared with CBZ (Schmutz et al. 1994; Stefani et al. 1997). The general OXC–CBZ mechanistic overlap is consistent with the hypothesis that OXC and CBZ have similar effects in bipolar disorder, which is consistent with preliminary clinical observations but remains to be established in large controlled clinical studies.

INDICATIONS AND EFFICACY

Seizure Disorders and Trigeminal Neuralgia

In the United States, CBZ is approved by the FDA as monotherapy for the treatment of trigeminal neuralgia and complex partial, generalized tonic–clonic, and mixed seizure disorders ("Carbatrol" 2008; "Tegretol" 2008). OXC is approved for the treatment of partial seizures as monotherapy in adults and as adjunctive therapy in adults and children older than 4 years ("Trileptal" 2008). CBZ and OXC appear to have overlapping anticonvulsant effects, with similar efficacy in patients with newly diagnosed epilepsy (Dam et al. 1989). However, there may be dissociations. For example, switching to OXC may be effective in patients with inadequate responses or intolerable adverse effects with CBZ (Beydoun et al. 2000; Van Parys and Meinardi 1994), and adding OXC may yield efficacy in patients with inadequate responses to CBZ (Barcs et al. 2000; Glauser et al. 2000). In contrast to valproate and lamotrigine, which are approved first-line medications for bipolar disorder, CBZ and OXC are generally considered alternative agents in the management of bipolar disorder (American Psychiatric Association 2002), based on the studies reviewed below.

Acute Mania

Twenty-three controlled studies have investigated CBZ and OXC efficacy in acute mania (Table 37–1) (Ballenger and Post 1978; D. Brown et al. 1989; Desai et al. 1987; Emrich 1990; Emrich et al. 1985; Goncalves and Stoll 1985; Grossi et al. 1984; Klein et al. 1984; Lenzi et al. 1986; Lerer et al. 1987; Lusznat et al. 1988; Möller et al. 1989; Müller and Stoll 1984; Okuma et al. 1979, 1989, 1990; Post et al. 1987; Small et al. 1991; Stoll et al. 1986; Wagner et al. 2006; Weisler et al. 2004, 2005; Zhang et al. 2007). In these studies, there is more compelling evidence for CBZ efficacy (18 studies including 594 patients receiving CBZ) than for OXC efficacy (5 studies including 119 patients receiving OXC).

[a]Weighted means of patients with response data.

Two recent trials, which found a proprietary CBZ beaded extended-release capsule formulation (Equetro) superior to placebo, are of particular interest because they used a randomized, double-blind, placebo-controlled paradigm (Weisler et al. 2004, 2005) and yielded an FDA indication for the treatment of acute manic and mixed episodes in patients with bipolar disorder.

These recent reports are consistent with multiple earlier studies using placebo–drug–placebo, active-comparator (lithium or neuroleptics), and adjunctive (compared with placebo, lithium, or neuroleptics added to lithium or neuroleptics) designs. Thus, across studies that used diverse paradigms (see Table 37–1), overall antimanic response rates were generally comparable to those seen with lithium or neuroleptics or in other studies with valproate (Ketter 2005). Taken together, this collection of clinical trials provides substantial evidence for the acute antimanic efficacy of CBZ and preliminary evidence for the acute antimanic efficacy of OXC. For CBZ, this current body of existing data appears greater than that initially considered by the FDA in approving lithium for the treatment of acute mania.

Improvement appears to occur across the entire manic syndrome and does not seem to be due to nonspecific sedative properties, in that patients often show dramatic clinical improvement in the absence of marked sedation. Because CBZ and OXC are frequently used in combination with other medications in the acute treatment of mania, knowledge of CBZ's extensive and OXC's more limited drug–drug interactions (as described later in this chapter) is often required to achieve optimal outcomes.

Acute Depression

There are limited controlled data regarding the acute antidepressant effects of CBZ, and no published controlled studies of the antidepressant effects of OXC (Table 37–2). Although CBZ appears to have weaker antidepressant than antimanic properties, some evidence suggests that it may provide antidepressant benefit in about one-third of treatment-resistant patients (Neumann et al. 1984; Post et al. 1986; Small 1990), and in a Chinese study, CBZ yielded a response rate closer to two-thirds in non-treatment-resistant patients (Zhang et al. 2007). Unfortunately, most of these studies are limited by the use of small samples of heterogeneous (both bipolar and unipolar) and highly treatment-resistant patients. Nevertheless, double-blind off–on–off–on observations and a randomized, double-blind, placebo-controlled trial have provided evidence of individual responsiveness in at least a subgroup of depressed bipolar patients.

Prophylaxis

Findings from a series of 16 double-blind, randomized, open randomized, or otherwise partially controlled studies (Ballenger and Post 1978; Bellaire et al. 1988; Cabrera et al. 1986; Coxhead et al. 1992; Denicoff et al. 1997; Di

Costanzo and Schifano 1991; Elphick et al. 1988; Greil et al. 1997; Hartong et al. 2003; Kishimoto and Okuma 1985; Lusznat et al. 1988; Mosolov 1991; Okuma et al. 1981; Placidi et al. 1986); Post et al. 1983b; Watkins et al. 1987; Wildgrube 1990) are consistent with a very substantial open literature suggesting that CBZ may be effective in preventing bipolar manic and depressive episodes when administered as long-term prophylaxis, either alone or in combination with lithium, in patients who previously had not responded to lithium (Table 37–3). CBZ may have equal *prophylactic* antidepressant and antimanic efficacy, in contrast to its less potent *acute* antidepressant versus antimanic effects. In contrast, there are only sparse data regarding the efficacy of OXC in the prophylaxis of episodes in patients with bipolar disorder.

[a]Weighted means of patients with response data.

In one study, the overall analysis suggested that maintenance treatment was more effective with lithium than with CBZ (Greil et al. 1997), but subsequent analysis revealed subgroup differences. Thus, maintenance treatment was

more effective with lithium than with CBZ in patients with "classic" bipolar disorder (bipolar I disorder with no mood-incongruent delusions or comorbidity) but tended to be more effective with CBZ than with lithium in patients with "nonclassic" bipolar disorder (bipolar II disorder, bipolar disorder not otherwise specified, bipolar disorder with mood-incongruent delusions or comorbidity) (Greil et al. 1998).

In another study, maintenance treatment appeared to be more effective with lithium than with CBZ in patients with no more than 6 months' prior exposure to either agent (Hartong et al. 2003). However, this advantage was offset by more early discontinuations in the lithium group, so that similar proportions (about one-third) of lithium-treated and CBZ-treated patients completed 2 years with no episode. Patients on lithium compared to CBZ tended to have a somewhat greater risk of episodes in the first 3 months and markedly less risk of episodes after the first 3 months, with a recurrence risk of only 10% per year with lithium after the first 3 months. Patients on CBZ had a more consistent rate of relapse/recurrence of about 40% per year.

Some CBZ prophylaxis trials have been criticized due to methodological limitations (D. J. Murphy et al. 1989), but such difficulties are common in maintenance studies. For example, apparently due in part to methodological limitations, divalproex and lithium failed to separate from placebo on the primary efficacy measure in a 1-year maintenance study (Bowden et al. 2000). Taken together, the randomized, placebo-controlled, placebo–drug–placebo, and lithium comparator studies and trials in patients with rapid-cycling or lithium-resistant illness constitute substantial evidence for the efficacy of CBZ (Prien and Gelenberg 1989). CBZ may be effective in some individuals with valproate-resistant illness (Post et al. 1984b), and the CBZ plus valproate combination may be effective in patients who show little or no response to either agent alone (Keck et al. 1992; Ketter et al. 1992).

In a retrospective study, although 22 of 34 (65%) patients with treatment-resistant bipolar disorder responded to primarily adjunctive open CBZ acutely, when patients were assessed 3–4 years later, only 7 of 34 (21%) and 2 of 34 (6%) were considered probable and clear responders, respectively (Frankenburg et al. 1988). Post et al. (1990) have suggested that loss of CBZ prophylactic efficacy over time may be related to a unique form of contingent tolerance. In these instances, the optimal algorithm for recapturing CBZ response has not been determined. However, techniques such as switching to another treatment regimen with a different mechanism of action or returning later to CBZ (after a period of not taking CBZ) are worth considering, based on case reports and anecdotal observations. Systematic clinical trials are required to better determine the efficacy of these and other approaches for recapturing CBZ response.

Response Predictors

Predictors of CBZ and OXC response have not been adequately elucidated. CBZ appears to be effective in patients with a history of lithium unresponsiveness or intolerance (Okuma et al. 1979; Post et al. 1987). Nonclassic bipolar disorder (Greil et al. 1998; Small et al. 1991) and stable or decreasing episode frequency (Post et al. 1990) have been reported to be associated with CBZ response. Studies have indicated that patients with a history of affective illness in first-degree relatives may have preferential responses to lithium, whereas the converse may be the case for CBZ (Ballenger and Post 1978; Post et al. 1987). Himmelhoch and colleagues (Himmelhoch 1987; Himmelhoch and Garfinkel 1986) have suggested that patients with comorbid neurological or substance abuse problems and inadequate lithium responses might respond to CBZ or valproate. Preliminary observations indicate that baseline cerebral (left insula) hypermetabolism may be a marker of CBZ response (Ketter et al. 1999).

There are varying reports with respect to the relationships between CBZ response and dysphoric manic presentations (Lusznat et al. 1988; Post et al. 1989) and illness severity (Post et al. 1987; Small et al. 1991). Although several investigators have suggested that psychosensory symptoms (which have been hypothesized to be due to limbic dysfunction) may indicate preferential response to CBZ and other anticonvulsants, such a relationship has not been observed in acute therapy, and the relationship to prophylactic response remains to be delineated.

Antidepressant responses to CBZ may be seen in patients with more severe depression, more discrete depressive episodes, less chronicity, and greater decreases in serum T_4 concentrations with CBZ (Post et al. 1991, 1986).

Although the initial studies of Post et al. (1987) and Okuma et al. (1981; Okuma 1983) indicated that some rapid-cycling patients were responsive to CBZ, other investigators found less robust results (Dilsaver et al. 1993; Joyce 1988). As with lithium, later studies by Okuma (1993) reported a lower CBZ maintenance response rate in rapid-cycling compared with non-rapid-cycling illness. However, even these rapid-cycling patients had a CBZ response rate (40%) that was higher than the rates reported for other agents in other studies. Denicoff et al. (1997) also observed that patients with a history of rapid cycling had a lower CBZ maintenance response rate compared with

those without such a history (19% vs. 54%).

SIDE EFFECTS AND TOXICOLOGY

Baseline evaluation of bipolar disorder patients includes not only psychosocial assessment but also general medical evaluation, in view of the risk of medical processes, which could confound diagnosis or influence management decisions, and the risk of adverse effects, which may occur with treatment. Assessment commonly includes history; physical examination; complete blood count with differential and platelets; renal, hepatic, and thyroid function; toxicology; pregnancy tests; and other chemistries and electrocardiogram as clinically indicated (American Psychiatric Association 2002). Such evaluation provides baseline values for parameters that influence decisions about choice of medication and intensity of clinical and laboratory monitoring.

Carbamazepine

CBZ adverse effects appear to have substantial impact on the utility of CBZ in the treatment of bipolar disorder. For example, in a retrospective study, 12 of 55 (22%) patients with treatment-resistant psychotic disorders (including 34 with bipolar disorder) discontinued primarily adjunctive open CBZ in the first 2 months because of adverse effects (Frankenburg et al. 1988). Also, in a randomized, double-blind crossover maintenance study, significantly more patients receiving CBZ (10 of 46, 22%) than those receiving lithium (2 of 50, 4%) discontinued the drug early because of adverse effects (Denicoff et al. 1997). In a randomized open maintenance study, although nonsignificantly more CBZ (9 of 70, 13%) than lithium (4 of 74, 5%) patients discontinued early because of adverse effects, significantly more CBZ (26 of 33, 79%) than lithium (20 of 51, 39%) patients who completed the study were free of adverse effects (Greil et al. 1997). Thus, adverse effects requiring discontinuation may occur more commonly with CBZ than with other drugs, particularly during acute therapy if CBZ is rapidly introduced. However, some patients may tolerate CBZ better than other agents, particularly during longer-term treatment, as CBZ appears to have a low propensity to cause adverse effects such as weight gain and metabolic disturbance that can limit the utility of some other agents (Ketter et al. 2005).

CBZ has several common dose-related adverse effects that can generally be minimized by attention to drug–drug interactions and gradual titration of dosage or reversed by decreasing dosage. At high doses, patients can develop neurotoxicity with sedation, ataxia, diplopia, and nystagmus, particularly early in therapy before autoinduction and the development of some tolerance to CBZ's central nervous system adverse effects occur. However, in contrast to neuroleptic treatment, CBZ therapy is not associated with extrapyramidal adverse effects. Because there is wide interindividual variation in susceptibility to adverse effects at any given concentration, it is most useful clinically to titrate doses against each patient's adverse effects rather than targeting a fixed dosage or serum concentration range.

Dizziness, ataxia, or diplopia emerging 1–2 hours after an individual dose is often a sign that the adverse-effect threshold has been exceeded and that dosage redistribution (spreading out the dose or giving more of the dosage at bedtime) or dosage reduction may be required. Use of extended-release formulations can also attenuate CBZ peak serum concentrations, enhancing tolerability.

The United States prescribing information for carbamazepine includes black box warnings regarding the risks of aplastic anemia (16 per million patient-years) and agranulocytosis (48 per million patient-years), as well as serious dermatological reactions and the HLA-B*1502 allele. Other warnings include the risks of teratogenicity, and increased intraocular pressure due to mild anticholinergic activity. Thus, CBZ can yield hematological (benign leukopenia, benign thrombocytopenia), dermatological (benign rash), electrolyte (asymptomatic hyponatremia), and hepatic (benign transaminase elevations) problems. Much less commonly, CBZ can yield analogous serious problems. For example, mild leukopenia and benign rash occur in as many as 1 of 10 patients, with the slight possibility that these usually benign phenomena are heralding malignant aplastic anemia and Stevens-Johnson syndrome/toxic epidermal necrolysis, seen in approximately 1 per 100,000 and 1 to 6 per 10,000 patients, respectively (Kramlinger et al. 1994; Tohen et al. 1995). Recent evidence indicates that the risk of serious rash may be 10 times as high in some Asian countries and strongly linked to the HLA-B*1502 allele. Thus, the United States prescribing information states that individuals of Asian descent should be genetically tested before initiating carbamazepine therapy. An individual who is HLA-B*1502 positive should not be treated with CBZ unless the benefit clearly outweighs the risk. In view of the risk of rare but serious decreases in blood counts, it is important to alert patients to seek immediate medical evaluation if they develop signs and symptoms of possible hematological reactions, such as fever, sore throat, oral ulcers, petechiae, and easy bruising or bleeding. Hematological monitoring needs to be intensified in patients with low or marginal leukocyte counts, and CBZ is generally discontinued if the leukocyte count falls below 3,000/mm^3 or the granulocyte count below 1,000/mm^3.

In early 2008, the FDA released an alert regarding increased risk of suicidality (suicidal behavior or ideation) in patients with epilepsy as well as psychiatric disorders for 11 anticonvulsants (including CBZ and OXC). In the FDA's analysis, anticonvulsants compared with placebo yielded approximately twice the risk of suicidality (0.43% vs. 0.22%). The relative risk for suicidality was higher in patients with epilepsy than in patients with psychiatric disorders. As of late 2008, a class warning regarding this risk had not yet been added to the United States prescribing information for anticonvulsants, but it is anticipated that this may occur.

In the instance of benign leukopenia, the addition of lithium can increase the neutrophil count back toward normal (Kramlinger and Post 1990), but this strategy is not likely to be helpful for the suppression of red cells or platelets, which is likely to be indicative of a more problematic process.

Rash presenting with systemic illness or involvement of the eyes, mouth, or bladder (dysuria) constitutes a medical emergency, and CBZ should be discontinued immediately and the patient assessed emergently. For more benign presentations, CBZ is generally discontinued, as there is little ability to predict which rashes will progress to more severe, potentially life-threatening problems. However, in rare instances of resistance to all medications except CBZ, a repeat trial of CBZ with a course of prednisone has usually been well tolerated (J. M. Murphy et al. 1991; Vick 1983). If there is evidence of systemic allergy, fever, or malaise, prednisone is less likely to be helpful. A substantial number of patients with CBZ-induced rashes may not have a rash on reexposure (even without prednisone coverage), but if a rash again develops, it usually appears more rapidly than in the first occurrence. Only 25%–30% of the patients who develop a rash while taking CBZ also develop a rash (cross-sensitivity) with OXC.

Due to the risk of rare hepatitis, patients should be advised to seek medical evaluation immediately if they develop malaise, abdominal pain, or other marked gastrointestinal symptoms. In general, CBZ (like other anticonvulsants) is discontinued if liver function tests exceed three times the upper limit of the normal range (Martinez et al. 1993).

CBZ may affect cardiac conduction and should be used with caution in patients with cardiac disorders such as heart block. A baseline electrocardiogram is worth considering if the patient has a positive cardiac history.

Conservative laboratory monitoring during CBZ therapy includes baseline studies and reevaluation of complete blood count, differential, platelets, and hepatic indices initially at 2, 4, 6, and 8 weeks, and then every 3 months (American Psychiatric Association 1994, 2002). Most of the serious hematological reactions occur in the first 3 months of therapy (Tohen et al. 1995). In contemporary clinical practice, somewhat less focus is placed on scheduled monitoring; instead, monitoring as clinically indicated (e.g., when a patient becomes ill with a fever) is emphasized. Patients who have abnormal or marginal indices at any point merit careful scheduled and clinically indicated monitoring. The United States prescribing information for the beaded extended-release capsule CBZ formulation that was recently approved for the treatment of acute mania includes monitoring baseline complete blood count, platelets, ±reticulocytes, ±serum iron, and hepatic function tests; closely monitoring patients with low or decreased white blood cell count or platelets; and considering discontinuation of CBZ if there is evidence of bone marrow depression ("Equetro" 2008). Serum CBZ concentrations are typically assessed at steady state and then as clinically indicated (e.g., by inefficacy or adverse effects).

Dividing or reducing doses, moving doses in relation to mealtimes, and changing formulations can attenuate CBZ-induced gastrointestinal disturbances. CBZ suspension may have more proximal absorption and thus exacerbate upper gastrointestinal (nausea and vomiting) or attenuate lower gastrointestinal (diarrhea) adverse effects. The reverse holds for extended-release preparations.

Weight gain and obesity are important clinical concerns in the management of bipolar disorder. Medications and the hyperphagia, hypersomnia, and anergy commonly seen in bipolar depression can contribute to this important obstacle to optimal outcomes. CBZ is less likely than lithium (Coxhead et al. 1992; Denicoff et al. 1997) or valproate (Mattson et al. 1992) to yield weight gain. In one study, CBZ caused weight gain in depressed (but not manic) patients, an effect that seemed to be related to the degree of relief of depression (Joffe et al. 1986b). Nevertheless, in view of its relatively favorable effect on weight, CBZ may provide an important alternative to other mood stabilizers for patients who struggle with weight gain and obesity.

CBZ can induce hyponatremia that may be tolerated well by some younger patients but can be particularly problematic in the elderly. If confusion develops in an elderly patient, serum sodium should be assessed. In rare instances water intoxication and seizures can occur. In some cases, hyponatremia can be effectively counteracted with the addition of lithium or the antibiotic demeclocycline (Ringel and Brick 1986).

CBZ increases plasma high-density lipoprotein (HDL) (O'Neill et al. 1982) and total cholesterol (D. W. Brown et al.

1992) concentrations. However, because the ratio of HDL to total cholesterol does not change (O'Neill et al. 1982), CBZ-induced increases in total cholesterol are not likely to be clinically problematic in regard to atherosclerosis (D. W. Brown et al. 1992).

CBZ decreases serum T_4, free T_4 index, and, less consistently, triiodothyronine (T_3) (Bentsen et al. 1983; Connell et al. 1984; Haidukewych and Rodin 1987; Joffe et al. 1986a) but does not substantially alter serum thyroid-binding globulin, reverse T_3, basal thyroid-stimulating hormone (TSH) concentrations (Bentsen et al. 1983; Connell et al. 1984), or somatic basal metabolic rates (Herman et al. 1991). In contrast to lithium, the TSH response to thyrotropin-releasing hormone is blunted (Joffe et al. 1986a) or unaltered (Connell et al. 1984) with CBZ therapy, and clinical hypothyroidism during treatment with CBZ is exceedingly rare.

CBZ is teratogenic (Pregnancy Category D) and is associated with low birth weight, craniofacial deformities, digital hypoplasia, and (in approximately 3% of exposures) spina bifida (Jones et al. 1989; Rosa 1991). For the latter, folate supplementation may attenuate the risk, and fetal ultrasound studies may allow early detection. In rare patients with severe mood disorders, clinicians may determine in consultation with a gynecologist that the benefits of treating with CBZ outweigh the risks in comparison with other treatment options (Sitland-Marken et al. 1989).

CBZ is present in breast milk at concentrations about half those present in maternal blood but may not accumulate in fetal blood (Froescher et al. 1984; Kuhnz et al. 1983; Pynnönen et al. 1977; Shimoyama et al. 2000). Clinicians may prefer to avoid the putative risks of exposing infants to CBZ in breast milk (Frey et al. 2002) and discourage breast-feeding in women taking CBZ ("Carbatrol" 2008; "Tegretol" 2008).

Oxcarbazepine

Adverse effects may limit the use of OXC, as with CBZ. In a retrospective study, adverse events were noted in one-third of 947 epilepsy patients (Friis et al. 1993). However, OXC may have tolerability advantages over CBZ, in part perhaps related to the absence of the CBZ-E metabolite. For example, in a 1-year randomized, double-blind study of 235 patients with newly diagnosed epilepsy, OXC monotherapy yielded fewer severe adverse effects than CBZ monotherapy (Dam et al. 1989). OXC and valproate may have similar tolerability; in a 1-year randomized, double-blind study of 249 patients with newly diagnosed epilepsy, monotherapy with these agents had similar rates of adverse effects (Christe et al. 1997). Importantly, OXC yielded anticonvulsant effects similar to those of CBZ and valproate in the above-mentioned studies.

Much less is known about the tolerability of OXC in bipolar disorder patients. In randomized, double-blind studies of monotherapy for acute mania, the proportions of patients experiencing adverse effects were lower with OXC 2,400 mg/day (2 of 19, 10%) than with high-dose haloperidol 42 mg/day (7 of 19, 37%) and were not statistically different with OXC 1,400 mg/day (8 of 29, 28%) compared with lithium 1,100 mg/day (5 of 27, 19%) (Emrich 1990). A retrospective study of open OXC in acutely manic inpatients found that by the time of discharge, only 6 of 200 (3%) had discontinued the medication because of adverse effects (3 due to hyponatremia) or potential drug–drug interactions (3 due to concomitant treatment with hormonal contraceptives) (Reinstein et al. 2002). However, in another retrospective study of primarily depressed patients with treatment-resistant bipolar disorder, 7 of 13 (54%) patients discontinued primarily adjunctive OXC because of adverse effects (Ghaemi et al. 2002).

OXC appears to yield less neurotoxicity and rash than CBZ. In a retrospective study of 947 epilepsy patients, OXC adverse effects most frequently involved the central nervous system and included dizziness, sedation, and fatigue, each of which was noted in 6% of patients (Friis et al. 1993). Rash was seen in 6% of patients, half of whom had previously experienced CBZ allergic reactions. About 75% of patients with a rash on CBZ will tolerate OXC. Importantly, OXC has not been associated with blood dyscrasias, lacks a boxed warning in the prescribing information, and does not appear to require hematological monitoring.

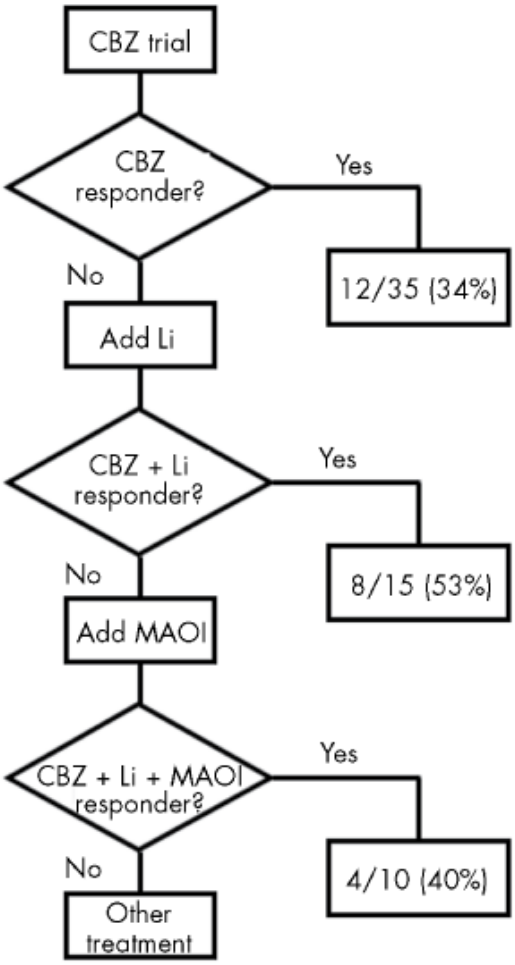
As noted earlier for CBZ, in early 2008 the FDA released an alert regarding increased risk of suicidality (suicidal behavior or ideation) in patients with epilepsy as well as psychiatric disorders for 11 anticonvulsants (including OXC and CBZ). As of late 2008, a class warning regarding this risk had not yet been added to the United States prescribing information for anticonvulsants, but it is anticipated that this may occur.

OXC, like CBZ, may produce transaminase elevations and gastrointestinal adverse effects but is associated with less weight gain than valproate (Rattya et al. 1999). In addition, OXC may have less impact on lipids than does CBZ; in 12 male patients with epilepsy, switching to OXC from CBZ yielded decreased serum total cholesterol (but not HDL cholesterol or triglyceride) concentrations (Isojarvi et al. 1994).

Hyponatremia occurs with OXC (Friis et al. 1993) and may be the main adverse effect that occurs more commonly

than with CBZ. In one study of 10 male epileptic patients who switched to OXC monotherapy from CBZ monotherapy, mean serum sodium concentrations decreased—in 2 of 10 (20%), below the reference range (Isojarvi et al. 2001a). However, clinically significant hyponatremia is less common than asymptomatic hyponatremia. In a retrospective study of inpatients with acute mania, OXC yielded serum sodium concentrations below the reference range in 24 of 200 (12%), but only 3 of 200 (1.5%) discontinued as a result of hyponatremia with serum sodium less than 125 mmol/L (Reinstein et al. 2002).

In comparison with CBZ, OXC has less impact on blood concentrations of thyroid and sex hormones, likely because of its less marked hepatic enzyme induction. In one study, only 24% of 29 male epileptic patients taking OXC—versus 45% of 40 taking CBZ—had low serum total and/or free T_4 (but not T_3 and thyrotropin) concentrations (Isojarvi et al. 2001b). In addition, male epileptic patients taking CBZ (but not those taking OXC) had decreased serum dehydroepiandrosterone sulfate concentrations (Rattya et al. 2001). Switching to OXC from CBZ in male epileptic patients yielded increased serum dehydroepiandrosterone sulfate concentrations (Isojarvi et al. 1995). In healthy male volunteers, higher (≥900 mg/day) but not lower (<900 mg/day) dosages of OXC appeared to yield increased levels of testosterone and gonadotropins (Larkin et al. 1991). Importantly, as noted below (see "Drug–Drug Interactions"), OXC induction of female hormone metabolism is sufficient to decrease the efficacy of hormonal contraceptives (Fattore et al. 1999; Klosterskov Jensen et al. 1992).



OXC, in contrast to CBZ, has not to date been associated with congenital malformations in humans (FDA Pregnancy Category C). This could be merely related to fewer OXC exposures. However, the absence of the CBZ-E metabolite could render OXC less teratogenic; in mice, CBZ-E (but not OXC) yielded two- to fourfold increases in malformations compared with placebo (Bennett et al. 1996). As with CBZ, in rare patients with severe mood disorders, clinicians may determine in consultation with a gynecologist that the benefits of treating with OXC outweigh the risks in comparison with other treatment options.

OXC is present in breast milk, and as with CBZ, clinicians may prefer to avoid the putative risks of exposing infants to OXC in breast milk and discourage breast-feeding in women taking OXC ("Trileptal" 2008).

DRUG–DRUG INTERACTIONS

Combination therapy is common in bipolar disorder, with up to two-thirds of patients receiving more than one medication (Kupfer et al. 2002). Patients with treatment-resistant illness may require a stepped-care approach (Figure 37–2) and appear to be receiving increasingly complex medication regimens (Frye et al. 2000). CBZ and, to a lesser extent, OXC have clinically significant drug–drug interactions, which increase the complexity of managing patients with bipolar disorder.

Composite schema of results from three different studies in which patients with bipolar depression received carbamazepine (CBZ) monotherapy (Post et al. 1986), lithium (Li) added to CBZ (Kramlinger and Post 1989b), and a monoamine oxidase inhibitor (MAOI) added to CBZ±Li (Ketter et al. 1995b). Each successive intervention yielded additional efficacy.

Carbamazepine

The pharmacokinetic properties of CBZ are typical of older enzyme-inducing anticonvulsants used by neurologists but atypical among medications prescribed by psychiatrists and necessitate special care when treating patients concurrently with other medications (Ketter et al. 1991a, 1991b). Three major principles appear to contribute importantly to CBZ drug–drug interactions:

1. **CBZ is a robust inducer of catabolic enzymes (including CYP3A3/4) and decreases the serum concentrations of many medications, including CBZ itself (Table 37–4).** CBZ induces not only CYP3A3/4 and conjugation but also presumably other cytochrome P450 isoforms that remain to be characterized. Thus, CBZ decreases the serum concentrations not only of CBZ itself (autoinduction) but also of many other medications (heteroinduction). CBZ-induced decreases in serum concentrations of certain concurrent medications can render them ineffective (see Table 37–4). Moreover, if CBZ is discontinued (or, in some instances, if replaced with OXC), serum concentrations of these other medications can increase, potentially leading to adverse effects.
2. **CBZ metabolism (which is primarily by CYP3A3/4) can be inhibited by certain enzyme inhibitors, yielding increases in serum CBZ concentrations and CBZ intoxication (Table 37–5; see Figure 37–1, top).** Autoinduction makes CBZ particularly vulnerable to the effects of enzyme inhibitors. Thus, a variety of agents that inhibit CYP3A3/4 can yield increased serum CBZ concentrations and intoxication (see Table 37–5; see Figure 37–1, top).
3. **CBZ has an active epoxide (CBZ-E) metabolite (see Figure 37–1, top).** Valproate inhibits epoxide hydrolase, yielding increased serum CBZ-E (but not CBZ) concentrations and intoxication (see Table 37–5). Free CBZ may also

increase because of valproate-induced displacement of CBZ protein binding.

Thus, CBZ has a wide variety of pharmacokinetic drug–drug interactions that are in excess of and different from those seen with lithium or valproate. Knowledge of CBZ drug–drug interactions is crucial in effective management, and patients should be instructed to consult their pharmacist when prescribed other medications by other physicians. Advances in molecular pharmacology have characterized the specific cytochrome P450 isoforms responsible for metabolism of various medications. This may allow clinicians to anticipate and avoid pharmacokinetic drug–drug interactions and thus provide more effective combination pharmacotherapies. Below, we review CBZ drug interactions with other medications, with agents of particular interest in the management of mood disorders indicated in boldface type. The reader interested in detailed reviews of CBZ drug–drug interactions may find these in other articles (Ketter et al. 1991a, 1991b).

Interactions With Mood Stabilizers

The combination of CBZ plus lithium is frequently used in bipolar disorder and may provide additive or synergistic antimanic (Kramlinger and Post 1989a) and antidepressant (Kramlinger and Post 1989b) effects. The combination is generally well tolerated, with merely additive neurotoxicity (McGinness et al. 1990), which can be minimized by gradual dose escalation. Pharmacokinetic interactions between these drugs do not occur, because lithium is excreted by the kidney, with no hepatic metabolism. Adverse effects of lithium and CBZ can be either additive or complementary, so that combination therapy decreases the serum concentrations of thyroid hormones in an additive fashion (Kramlinger and Post 1990), whereas lithium-induced increases in leukocytes and neutrophils override the common benign decreases in these indices seen with CBZ (Kramlinger and Post 1990). However, there is no evidence that lithium can alter the course of the rare severe bone marrow suppression caused by CBZ (Joffe and Post 1989). Also, the diuretic effect of lithium overrides the antidiuretic effect of CBZ (Klein 1987). Thus, CBZ will not reverse lithium-induced diabetes insipidus, but lithium attenuates CBZ-induced hyponatremia (Klein 1987; Vieweg et al. 1987).

Reports suggest that the CBZ plus valproate combination not only is tolerated but also may show psychotropic synergy (Keck et al. 1992; Ketter et al. 1992; Tohen et al. 1994). However, the effective use of these two medications together requires a thorough knowledge of their drug interactions, which can be simplified into the general principle that usual doses of CBZ should be reduced. Valproate inhibits CBZ metabolism (Macphee et al. 1988) and also displaces CBZ from plasma proteins, increasing the free CBZ fraction that is active and available to be metabolized (Macphee et al. 1988; Moreland et al. 1984). Depending on which effect predominates, total serum CBZ concentrations can rise (Moreland et al. 1984) or fall (Rambeck et al. 1987) or remain unchanged (Brodie et al. 1983; Kutt et al. 1985; Macphee et al. 1988). Valproate inhibits epoxide hydrolase, increasing the serum CBZ-E concentration, at times without altering the total serum CBZ concentration (Brodie et al. 1983; Rambeck et al. 1987).

Thus, these interactions can potentially confound clinicians, because patients can have neurotoxicity due to

elevated serum CBZ-E or free CBZ concentrations despite having therapeutic serum total CBZ concentrations (Kutt et al. 1985). CBZ decreases serum valproate concentrations (Kondo et al. 1990), and its discontinuation can yield increased serum valproate concentrations and toxicity (Jann et al. 1988). CBZ enzyme induction also increases the formation of the active valproate metabolite, 2-propyl-4-pentenoic acid (4-ene-valproate) (Kondo et al. 1990), which may be hepatotoxic and also may add to teratogenicity (Nau and Loscher 1986; Scheffner et al. 1988). Although fatal hepatitis in infants treated with combinations of valproate with other anticonvulsants is of great concern (Scheffner et al. 1988), the risk of combined therapy is much lower in adults (Dreifuss et al. 1989). As a general rule, clinicians should clinically monitor patients receiving the CBZ plus valproate combination for adverse effects and consider decreasing the CBZ dose in advance (because of the expected displacement of CBZ from plasma proteins and increase in CBZ-E) and possibly increasing the valproate dose (because of expected CBZ-induced decrements in valproate).

CBZ increases lamotrigine metabolism and approximately halves blood lamotrigine concentrations. Thus, lamotrigine doses can be doubled with this combination. In addition, CBZ combined with lamotrigine may have additive neurotoxicity, probably due to a pharmacodynamic interaction. CBZ even appears to affect OXC metabolism; in patients with epilepsy, CBZ yielded decreased serum MHD concentrations (McKee et al. 1994).

Interactions With Antidepressants

Antidepressants are commonly combined with mood stabilizers in the treatment of bipolar disorder. Because CBZ can increase metabolism of some antidepressants, and because some antidepressants can inhibit CBZ metabolism, dosage adjustments may be necessary in combination therapy.

Selective serotonin reuptake inhibitors (SSRIs) have fewer adverse effects than do older antidepressants, but paroxetine and fluoxetine potently inhibit CYP2D6 (but not CYP1A2), and fluvoxamine inhibits CYP1A2 (but not CYP2D6). The atypical antidepressant nefazodone, norfluoxetine, and to a lesser extent fluvoxamine appear to inhibit CYP3A4 (Brosen 1994). Fluoxetine (Grimsley et al. 1991; Pearson 1990), fluvoxamine (Fritze et al. 1991), and nefazodone (Ashton and Wolin 1996; Laroudie et al. 2000; Roth and Bertschy 2001) have been reported to inhibit CBZ metabolism, causing increased CBZ concentrations and toxicity, although evidence to the contrary also has emerged for fluoxetine and fluvoxamine (Spina et al. 1993). Viloxazine (Pisani et al. 1984, 1986) and perhaps trazodone (Romero et al. 1999) can also increase CBZ levels.

Taken together, these observations suggest that fluoxetine, fluvoxamine, and nefazodone may increase CBZ concentrations, possibly by inhibition of CYP3A4. In addition, parkinsonian symptoms have been reported after addition of fluoxetine to CBZ (Gernaat et al. 1991). In contrast, sertraline (Rapeport et al. 1996), paroxetine (Andersen et al. 1991), citalopram (Moller et al. 2001), and mirtazapine (Sitsen et al. 2001) do not appear to alter CBZ metabolism. CBZ appears to decrease serum concentrations of racemic citalopram, including those of the active enantiomer escitalopram (Steinacher et al. 2002). CBZ also appears to induce the metabolism of mirtazapine (Sitsen et al. 2001), mianserin (Eap et al. 1999), sertraline (Khan et al. 2000; Pihlsgard and Eliasson 2002), and to some extent trazodone (Otani et al. 1996), but not viloxazine (Pisani et al. 1986). The combination of CBZ with mirtazapine is of potential concern given that mirtazapine has been associated with rare agranulocytosis, and CBZ could induce metabolism of this drug, decreasing plasma mirtazapine concentrations.

Patients receiving CBZ and bupropion have extremely low serum bupropion concentrations and high hydroxybupropion (metabolite) concentrations (Ketter et al. 1995a). Because hydroxybupropion is active, the clinical impact of this dramatic decrease in the bupropion-to-hydroxybupropion ratio is probably not problematic, and the combination of CBZ and bupropion may often be effective and well tolerated.

Theoretical grounds have been stated for concern about combining CBZ with monoamine oxidase inhibitors (MAOIs) ("Carbatrol" 2008; "Tegretol" 2008; Thweatt 1986). CBZ may increase rather than decrease serum levels of transdermal selegiline and its metabolites ("Emsam" 2008), and higher CBZ doses were needed in five patients taking tranylcypromine than in four taking phenelzine to yield similar serum CBZ concentrations (Barklage et al. 1992). However, case reports (Joffe et al. 1985; Yatham et al. 1990) and a series of 10 patients (Ketter et al. 1995b) suggest that the addition of phenelzine or tranylcypromine to CBZ may be well tolerated, does not affect CBZ pharmacokinetics, and may provide relief of resistant depressive symptoms in some patients. However, the antituberculosis drug isoniazid, which is also an MAOI, increases CBZ levels.

CBZ appears to induce the metabolism of tricyclic antidepressants (TCAs), including amitriptyline (Leinonen et al. 1991), nortriptyline (Brosen and Kragh-Sorensen 1993), imipramine (C. S. Brown et al. 1990), desipramine (Baldessarini et al. 1988), doxepin (Leinonen et al. 1991), and clomipramine (De la Fuente and Mendlewicz 1992),

so that if patients fail to respond to standard doses of TCAs, TCA and metabolite concentrations should be checked. CBZ-induced decreases in tertiary-amine TCA concentrations could be mediated by CYP3A4 induction, because this isoenzyme (as well as CYP1A2 and CYP2D6) has been implicated in the *N*-demethylation of imipramine but not desipramine (Lemoine et al. 1993; Ohmori et al. 1993). The mechanism of possible CBZ induction of secondary-amine TCA metabolism remains to be determined. Spina et al. (1994) suggested that induction of CYP2D6 (the isoenzyme responsible for TCA 2-hydroxylation) may be the operative process, although no other medication has been observed to definitely yield significant induction of this isoenzyme.

Interactions With Antipsychotics

Combinations of antipsychotics with mood stabilizers are commonly required in treatment of severe mania (American Psychiatric Association 2002). Newer antipsychotics are preferred over older antipsychotics in the management of bipolar disorder because of their better tolerability (American Psychiatric Association 2002). CBZ can be used effectively in combination with antipsychotics, although clinicians need to be aware of potential drug–drug interactions.

CBZ increases haloperidol metabolism (Ereshefsky et al. 1986; Jann et al. 1989; Kahn et al. 1990), dramatically lowering its blood concentrations. Haloperidol metabolism is complex (Tsang et al. 1994), and the mechanism of CBZ induction of this metabolism remains to be determined. Some patients have improvement in psychiatric status or fewer neuroleptic adverse effects during combination treatment, while others show deterioration in psychiatric status (Jann et al. 1989; Kahn et al. 1990). Neurotoxicity possibly related to receiving the combination of CBZ and haloperidol has been very rarely reported (Brayley and Yellowlees 1987). There is weaker evidence that CBZ may increase the metabolism of other first-generation antipsychotic agents, including fluphenazine (Ereshefsky et al. 1986; Jann et al. 1989), chlorpromazine (Raitasuo et al. 1994), and thiothixene (Ereshefsky et al. 1986), but not thioridazine (Tiihonen et al. 1995), and that loxapine, chlorpromazine, and amoxapine may increase CBZ-E concentrations (Pitterle and Collins 1988). Thioridazine does not yield clinically significant changes in serum CBZ or CBZ-E concentrations (Spina et al. 1990). Also, animal studies suggest that promazine, chlorpromazine, perazine, chlorprothixene, and flupenthixol may increase CBZ concentrations (Daniel et al. 1992). In view of the above, serum antipsychotic medication concentrations should be checked if patients fail to respond to standard dosages of antipsychotic agents during combination therapy with CBZ.

Combination of clozapine with CBZ is not recommended in view of the hypothetical possibility of synergistic bone marrow suppression ("Carbatrol" 2008; "Tegretol" 2008). However, these drugs have been used in combination in some European centers, one of which reported that CBZ decreases clozapine (a CYP2D6 substrate [Fischer et al. 1992]) concentrations (Raitasuo et al. 1993). Thus, clinicians wishing to combine a psychotropic anticonvulsant with clozapine should consider valproate, lamotrigine, or another anticonvulsant rather than CBZ, except under unusual circumstances.

CBZ increases metabolism of olanzapine (Linnet and Olesen 2002; Lucas et al. 1998), risperidone (Ono et al. 2002; Spina et al. 2000; Yatham et al. 2003), quetiapine (Grimm et al. 2006), aripiprazole (Physicians' Desk Reference 2008), and ziprasidone (Miceli et al. 2000). Although the clinical significance of CBZ-induced decreases in ziprasidone serum concentrations remains to be determined, CBZ interactions with other atypical antipsychotics can be clinically significant. For example, in a recent acute mania combination therapy study, CBZ decreased serum risperidone plus active metabolite concentrations by 40%, interfering with antipsychotic efficacy (Yatham et al. 2003). In another combination therapy study, CBZ yielded lower-than-expected blood olanzapine concentrations, and even though this was addressed in part by more aggressive olanzapine dosage, the efficacy of the olanzapine plus CBZ combination was still not significantly better than that of CBZ monotherapy in the treatment of acute mania (Tohen et al. 2008). In two patients, quetiapine appeared to increase CBZ-E levels (Fitzgerald and Okos 2002). The effects of clozapine, olanzapine, risperidone, ziprasidone, and aripiprazole on CBZ pharmacokinetics remain to be established.

Interactions With Anxiolytics and Sedatives

CBZ is commonly administered along with benzodiazepines in patients with bipolar disorder, with merely additive central nervous system (e.g., sedation, ataxia) adverse effects. Indeed, contemporary controlled CBZ trials routinely permit some adjunctive benzodiazepine (e.g., lorazepam) administration (Weisler et al. 2004, 2005). However, CBZ may decrease serum concentrations of clonazepam (Lai et al. 1978; Yukawa et al. 2001), alprazolam (Arana et al. 1988; Furukori et al. 1998), clobazam (Levy et al. 1983), and midazolam (Backman et al. 1996), potentially decreasing the efficacy of these agents. CBZ-induced decreases in certain benzodiazepine concentrations could be mediated by induction of CYP3A4, as this isoenzyme has been implicated in the

metabolism of clonazepam (Seree et al. 1993), triazolam (Kronbach et al. 1989), midazolam (Gascon and Dayer 1991; Kronbach et al. 1989), and possibly alprazolam (Greenblatt et al. 1993; von Moltke et al. 1993). The newer hypnotics eszopiclone and zolpidem may have drug interactions with CBZ, as these agents appear to be more susceptible than zaleplon to drugs that induce CYP3A4 (Drover 2004). On the other hand, clonazepam (Lander et al. 1975; Lehtovaara et al. 1978) and clobazam (Goggin and Callaghan 1985; Munoz et al. 1990) appear to have variable effects on CBZ metabolism. Of interest, CBZ may be effective in ameliorating benzodiazepine withdrawal symptoms (Ries et al. 1989).

Interactions With Stimulants

The use of stimulants in bipolar disorder is circumscribed largely because of concerns about the risk of abuse and mood destabilization. CBZ appears to decrease serum concentrations of methylphenidate and modafinil.

Interactions With Calcium Channel Blockers

Of clear clinical importance, elevated serum CBZ concentrations and neurotoxicity have been reported during concurrent treatment with the nondihydropyridines verapamil and diltiazem, but not the dihydropyridines nifedipine (Brodie and MacPhee 1986; Price and DiMarzio 1988) and nimodipine. (This is easily remembered by the "N" rule: Not Nifedipine or Nimodipine.) These observations are consistent with the finding that verapamil and diltiazem, but not nifedipine, inhibit the hepatic oxidative metabolism of various drugs (Hunt et al. 1989). Preliminary observations also indicate that the dihydropyridine nimodipine may not substantially influence CBZ kinetics and that the addition of CBZ to nimodipine may yield therapeutic synergy (Pazzaglia et al. 1993, 1998).

Enzyme-inducing anticonvulsants such as CBZ appear to decrease serum concentrations of dihydropyridines such as nimodipine (Tartara et al. 1991) and felodipine (Capewell et al. 1988; Zaccara et al. 1993), presumably by induction of CYP3A4, given that this isoenzyme mediates metabolism of nimodipine, felodipine, nifedipine, and nicardipine, as well as a variety of other dihydropyridines (Guengerich et al. 1991).

Interactions With Substances of Abuse

In view of the high comorbidity of bipolar disorder and alcohol abuse, knowledge of interactions between ethanol and CBZ is of clinical utility. Ethanol is a CYP2E1 substrate (Gonzalez et al. 1991) and inducer (Hansson et al. 1990). Although ethanol and CBZ do not have pharmacokinetic interactions (Dar et al. 1989; Pynnönen et al. 1978) (presumably because of their metabolism by different CYP families), CBZ attenuates alcohol withdrawal symptoms (Malcolm et al. 1989), a potentially useful property given the risk of alcohol abuse in bipolar disorder patients. Combination therapy with disulfiram and CBZ is well tolerated and does not cause clinically significant changes in serum CBZ and CBZ-E concentrations (Krag et al. 1981).

Tobacco smoking (which induces CYP1A [Guengerich 1992]) does not alter CBZ metabolism (Bachmann et al. 1990), and CBZ does not alter caffeine (a CYP1A2 substrate [Fuhr et al. 1992]) pharmacokinetics (Wietholtz et al. 1989).

Preliminary clinical studies suggested that CBZ attenuated acute cocaine effects and seizures and possibly cocaine craving (Halikas et al. 1989; Kuhn et al. 1989; Sherer et al. 1990), but later controlled studies generally failed to support these observations (Cornish et al. 1995; Kranzler et al. 1995; Montoya et al. 1994).

Interactions With Anticonvulsants

As noted above, CBZ induces the metabolism of carbamazepine (autoinduction) and oxcarbazepine (McKee et al. 1994), as well as the mood-stabilizing anticonvulsants valproate and lamotrigine. CBZ also induces the metabolism of several older anticonvulsants, including ethosuximide, phenytoin, and primidone. Moreover, CBZ induces the metabolism of multiple newer anticonvulsants, including felbamate, topiramate (Sachdeo et al. 1996), tiagabine (Samara et al. 1998), zonisamide (Ojemann et al. 1986), and possibly levetiracetam (May et al. 2003), but not gabapentin (Radulovic et al. 1994) or pregabalin (Brodie et al. 2005). In contrast, none (aside from felbamate) of these newer anticonvulsants yields clinically significant changes in CBZ pharmacokinetics (Brodie et al. 2005; Gidal et al. 2005; Gustavson et al. 1998; McKee et al. 1994; Radulovic et al. 1994; Ragueneau-Majlessi et al. 2004; Sachdeo et al. 1996). However, the anticonvulsants phenytoin, phenobarbital, primidone, methsuximide, and felbamate decrease serum CBZ concentrations. In addition, CBZ may have a pharmacodynamic interaction with levetiracetam (Sisodiya et al. 2002).

Interactions With Nonpsychotropic Drugs

Drug–drug interactions between CBZ and other (nonpsychotropic) drugs are also of substantial clinical importance.

CBZ induces metabolism of diverse medications, raising the possibility of undermining the efficacy of steroids such as hormonal contraceptives, dexamethasone, prednisolone, and mifepristone. In women taking CBZ, oral contraceptive preparations need to contain at least 50 μg of ethinylestradiol, levonorgestrel implants are contraindicated because of cases of contraceptive failure, and medroxyprogesterone injections need to be given every 10 rather than 12 weeks (Crawford 2002). CBZ also induces metabolism of methylxanthines such as theophylline and aminophylline; antibiotics such as doxycycline; antivirals such as protease inhibitors; neuromuscular blockers such as pancuronium, vecuronium, and doxacurium; analgesics such as methadone; immunosuppressants such as sirolimus and tacrolimus; and the anticoagulants warfarin and possibly dicumarol (see Table 37–4).

Similarly, a variety of medications can increase serum CBZ concentrations and yield clinical toxicity, including isoniazid, azole antifungals such as ketoconazole, macrolide antibiotics such as erythromycin and clarithromycin, protease inhibitors such as ritonavir and nelfinavir, hypolipidemics such as gemfibrozil and nicotinamide, and the carbonic anhydrase inhibitor acetazolamide (see Table 37–5). In addition, other medications such as cisplatin and doxorubicin may decrease serum CBZ levels, potentially yielding inefficacy.

Oxcarbazepine

In contrast to CBZ, OXC has fewer clinically significant drug–drug interactions. Differences in three major areas appear to contribute importantly to differences between OXC and CBZ drug–drug interactions:

1. **OXC is only a modest to moderate enzyme (CYP3A4) inducer, which yields clinically significant decreases in serum concentrations of some medications (see Table 37–4).** OXC yields minor enzyme heteroinduction (but not autoinduction), which is clearly less robust than that seen with CBZ. For example, in healthy male volunteers, measures of enzyme activity such as antipyrine metabolism and urinary 6-β-hydroxycortisol excretion concentrations were unaltered with OXC (Larkin et al. 1991), and in male epileptic patients, switching to OXC from CBZ yielded decreased antipyrine clearance (Isojarvi et al. 1994). In some instances, OXC compared to CBZ induction is substantially less robust, so that switching from OXC to CBZ (or vice versa) will make adjustments of doses of other medications necessary. The extent of OXC induction of metabolism of other drugs is often clinically insignificant but is clinically significant for hormonal contraceptives. Serum concentrations of some of the medications (in ***boldface italic*** type) listed in Table 37–4 may decrease to a clinically significant extent with OXC, hindering efficacy of such agents. OXC decreases serum concentrations of female hormones, presumably mediated by heteroinduction of CYP3A, sufficiently to compromise the efficacy of hormonal contraceptives (Fattore et al. 1999) and to require higher doses. In contrast, induction of conjugation is more limited, yielding only modest clinical effects on clearance of drugs such as valproate and lamotrigine. Finally, OXC inhibits CYP2C19 (Tripp et al. 1996) and thus may increase serum phenytoin concentrations.
2. **OXC metabolism (which is primarily by arylketone reductase) generally is not susceptible to enzyme inhibitors.** The absence of autoinduction and the robust actions of cytosol reductases that mediate conversion to MHD appear to render OXC metabolism not susceptible to the common phenomenon of inhibition by other agents seen with CBZ. Thus, the medications listed in Table 37–5 that can elevate serum CBZ concentrations and yield neurotoxicity do NOT appear to have such interactions with OXC.
3. **OXC has an active (MHD) metabolite (see Figure 37–1, bottom middle).** However, MHD metabolism, unlike CBZ-E catabolism, is not inhibited by valproate, presumably due to the lack of involvement of epoxide hydrolase in MHD disposition. Thus, coadministration of valproate does NOT yield toxicity related to increased MHD.

Interactions With Mood Stabilizers

OXC, in contrast to CBZ, does not induce valproate metabolism. In patients with epilepsy, OXC did not significantly alter valproate (or CBZ) area under the concentration–time curve (McKee et al. 1994), and switching to OXC from CBZ yielded increased serum total valproate concentration-to-dose ratios and increased valproate-related adverse effects (Battino et al. 1992). Also, in rats, valproate did not significantly alter OXC pharmacokinetic parameters (Matar et al. 1999).

OXC, in comparison with CBZ, also appears to have less robust effects on lamotrigine metabolism; in women with epilepsy, OXC was associated with a 29% and CBZ a 54% decrease in serum lamotrigine concentrations (May et al. 1999). The clinical significance of this interaction remains to be established and could vary across patients (Theis et al. 2005). Lamotrigine does not appear to alter OXC pharmacokinetics (Theis et al. 2005). A possible pharmacodynamic interaction has been reported with OXC and lamotrigine (Sabers and Gram 2000).

In addition, carbamazepine induces OXC metabolism, yielding decreased serum MHD concentrations (McKee et al. 1994). The presence or absence of pharmacokinetic interactions between OXC and lithium remains to be

established.

Interactions With Antidepressants

OXC, in contrast to CBZ, may not robustly induce citalopram metabolism; switching to OXC from CBZ in two patients yielded increased serum citalopram concentrations (Leinonen et al. 1996).

Interactions With Antipsychotics

OXC, unlike CBZ, may not robustly induce antipsychotic metabolism; switching to OXC from CBZ in six patients with schizophrenia or organic psychosis who were taking haloperidol, chlorpromazine, or clozapine yielded 50%–200% increases in serum neuroleptic concentrations and additional extrapyramidal symptoms (Raitasuo et al. 1994). OXC does not cause clinically significant alterations in serum olanzapine or risperidone concentrations (Rosaria Muscatello et al. 2005).

Interactions With Anxiolytics and Sedatives

OXC may decrease serum concentrations of benzodiazepines.

Interactions With Calcium Channel Blockers

OXC appears to decrease serum concentrations of dihydropyridine calcium channel blockers (which are CYP3A4 substrates) to some extent. Although OXC reduced felodipine area under the concentration–time curve by 28% in healthy volunteers, this effect was much smaller than that previously reported with CBZ (Zaccara et al. 1993). In a retrospective study, 16 inpatients with acute mania who were taking calcium channel blockers had no clinically significant changes in blood pressure when treated with concurrent OXC (Reinstein et al. 2002).

Interactions With Nonpsychotropic Drugs

OXC, compared with CBZ, also appears to have fewer interactions with nonpsychotropic drugs. Thus, neither the CYP3A4 inhibitor erythromycin (Keranen et al. 1992a) nor the heteroinhibitor cimetidine (Keranen et al. 1992b) appears to alter OXC pharmacokinetics in healthy volunteers. Also, OXC does not appear to robustly induce warfarin metabolism; in healthy volunteers receiving steady-state warfarin, OXC did not significantly alter prothrombin time (Kramer et al. 1992).

However, as noted earlier in this chapter, OXC appears to have a clinically significant interaction with hormonal contraceptives; in healthy female volunteers, OXC appeared to decrease ethinylestradiol and levonorgestrel derived from hormonal contraceptives by up to about 50% (Fattore et al. 1999; Klosterskov Jensen et al. 1992).

OXC, like CBZ, may decrease serum concentrations of the analgesic buprenorphine, the anticancer agent paclitaxel, and the antidiabetic agent repaglinide. As previously noted, OXC also yields decreases in serum concentrations of the dihydropyridine calcium channel blocker felodipine (which is also a CYP3A4 substrate). In contrast to CBZ, the CYP3A4 inhibitor erythromycin and the antidepressant viloxazine do not yield clinically significant increases in serum OXC concentrations.

OXC may modestly decrease serum concentrations of topiramate (May et al. 2002) and levetiracetam (May et al. 2003). In addition, the anticonvulsants CBZ, phenytoin, phenobarbital, and primidone may induce OXC metabolism. Finally, OXC can increase serum phenytoin concentrations, presumably by inhibiting the activity of CYP2C19.

CONCLUSION

In the past, because of lack of an FDA indication, complexity of use, and methodological concerns regarding earlier efficacy studies, CBZ was generally considered an alternative rather than a first-line intervention in bipolar disorder. However, the recent approval of a proprietary CBZ beaded extended-release capsule formulation (Equetro) for the treatment of acute manic and mixed episodes in patients with bipolar disorder and the low propensity of CBZ to cause weight gain and metabolic problems seen with some other agents may lead clinicians to reassess its role in the management of patients with bipolar disorder (Ketter et al. 2005). This long-acting preparation in some patients with bipolar disorder can be given as a single nighttime dose, which will enhance compliance and minimize daytime side effects.

OXC, compared with CBZ, has more limited evidence of efficacy in bipolar disorder but has enhanced tolerability and fewer drug–drug interactions. For example, with CBZ (but not OXC), common benign leukopenia is difficult to distinguish from what may be a harbinger of the very rare serious aplastic anemia, and patients and caregivers need to monitor carefully for symptoms of this adverse effect. In addition, CBZ (and to a lesser extent OXC) in combination therapy induces metabolism of other drugs, sometimes undermining their efficacy unless doses are

adjusted. Also, other drugs (such as erythromycin or verapamil) can inhibit CBZ (but not OXC) metabolism, causing CBZ toxicity. Instructing patients to alert their other caregivers and pharmacists that they are receiving CBZ may help avoid drug interactions. Informing patients of several of the common interactions can further assist in the warning process, as other practitioners may inadvertently introduce commonly used drugs such as erythromycin with the attendant risk of CBZ toxicity.

CBZ and OXC are important treatment options for bipolar disorder patients who experience inadequate responses to or unacceptable adverse effects with lithium and valproate. Awareness of CBZ and OXC pharmacology and potential drug–drug interactions will provide clinicians with the opportunity to enhance outcomes when managing bipolar disorder with these agents.

Chapter 38. Gabapentin and Pregabalin

GABAPENTIN

Anticonvulsants have long been used in the treatment of certain psychiatric conditions. As exemplified by the U.S. Food and Drug Administration (FDA) indications for divalproex sodium, carbamazepine, and lamotrigine in the acute and maintenance phases of bipolar disorder (Yatham et al. 2002), anticonvulsants are widely viewed as valid alternatives to, and in some cases preferred over, the conventional first-line psychopharmacotherapy choices of lithium and antipsychotics. Early observations of enhanced general well-being in epileptic patients treated with anticonvulsants, as well as various early hypotheses of kindling and sensitization proposed as models of affective illness progression (Weiss and Post 1998), have promoted controlled investigations of anticonvulsant drugs as potential mood-stabilizing agents.

Gabapentin is FDA approved for the adjunctive treatment of complex partial epilepsy with and without generalization and for the management of postherpetic neuralgia in adults. A retrospective review of five placebo-controlled trials of gabapentin in more than 700 patients with refractory partial seizure disorder additionally supported the concept of improvement in general well-being, prompting controlled investigation of the drug in primary psychiatric conditions (Dimond et al. 1996).

Pharmacological Profile and Mechanism of Action

The mechanism of gabapentin's anticonvulsant and psychotropic action is not fully understood. Gabapentin was originally developed as a γ-aminobutyric (GABA) analog. As reviewed by Taylor et al. (1998), GABA is the major inhibitory neurotransmitter in the cerebral cortex. Gabapentin does not act as a GABA precursor, agonist, or antagonist. Preclinical studies have suggested that gabapentin increases brain and intracellular GABA by an amino acid active transporter at the blood–brain barrier and multiple enzymatic regulatory mechanisms, respectively. For example, in vitro studies have shown that gabapentin increased the activity of glutamic acid decarboxylase, which is the enzyme that converts glutamate to GABA (Taylor et al. 1992). Conversely, gabapentin has been shown to inhibit GABA-transaminase (GABA-T), which is the enzyme primarily responsible for GABA catabolism (Loscher et al. 1991). Glutamate metabolism is also modulated by gabapentin. In vitro studies have demonstrated that gabapentin inhibits branched-chain amino acid aminotransferase (BCAA-T), an enzyme responsible for glutamate synthesis (Hutson et al. 1998), and activates glutamate dehydrogenase, an enzyme primarily involved in glutamate catabolism (Goldlust et al. 1995).

These enzymatic regulatory mechanisms that suggest an increased synthesis and decreased degradation of GABA are clinically relevant. Several, but not all, studies have reported decreased levels of cerebrospinal fluid (Gerner et al. 1996; Gold et al. 1980; Roy et al. 1991), plasma (Petty et al. 1990), and magnetic resonance (MR) spectroscopic GABA (Sanacora et al. 1999) in patients with affective illness in comparison with healthy controls. Furthermore, increased MR spectroscopic occipital GABA concentrations have been reported with serotonin reuptake inhibitor treatment in depressed patients (Sanacora et al. 2002) and gabapentin treatment in patients with complex partial epilepsy (Petroff et al. 1996).

Gabapentin has also been shown to bind to the α_2 subunit receptor of brain voltage-dependent

calcium channels, which may relate to the subsequent inhibition of monoaminergic transmission (Schlicker et al. 1985). There is no known direct activity at the dopamine, serotonin, benzodiazepine, or histamine receptors. However, gabapentin has been reported to increase whole-blood levels of serotonin in healthy controls (Rao et al. 1988). These potentially important mechanisms of action have not been tested formally in psychiatric patient populations.

Pharmacokinetics and Disposition

All bioavailability, distribution, and elimination parameters are based on the gabapentin molecule itself, as there is no active metabolite. Gabapentin exhibits nonlinear bioavailability most likely related to an active saturable L-amino acid transport carrier present in gut and blood–brain barrier (McLean 1999). There is no evidence of plasma protein binding, hepatic metabolism, or cytochrome P450 (CYP) autoinduction. Elimination half-life is 6–8 hours, with a recommended three-times-a-day dosing strategy. Gabapentin is eliminated from systemic circulation unchanged by renal excretion. Patients with compromised renal function will show evidence of reduced gabapentin clearance.

Indications and Efficacy

Epilepsy

Gabapentin currently is FDA approved as an adjunctive treatment for partial seizures with and without secondary generalization in adults with epilepsy ("Neurontin" 2006). This indication was based on controlled evaluations of gabapentin at daily doses of 600–1,800 mg. Additional research has reported efficacy and tolerability for gabapentin monotherapy at daily dosages up to 4,800 mg in patients with refractory epilepsy (Beydoun et al. 1998). There is no established therapeutic plasma level for seizure control. Gabapentin has a highly desirable side-effect profile. Only mild side effects (sedation, dizziness, and ataxia) have been commonly reported.

Nonepilepsy Neurological Conditions

Neuropathic pain

On the basis of two placebo-controlled studies (Rice et al. 2001; Rowbotham et al. 1998), gabapentin has received FDA approval for use in the management of postherpetic neuralgia in adults. Gabapentin has also been systemically evaluated in diabetic neuropathy (Backonja et al. 1998).

The initial postherpetic neuralgia (Rowbotham et al. 1998) and diabetic neuropathy (Backonja et al. 1998) studies were randomized, double-blind, placebo-controlled, parallel-group multicenter investigations with three phases of evaluation. The first phase identified the subject population (patients with diabetic neuropathy of 1–5 years' duration [Backonja et al. 1998] or postherpetic neuralgia of 3 months' duration [Rowbotham et al. 1998]). The 8-week double-blind phases consisted of a 4 week step titration (week 1, 900 mg; week 2, 1,800 mg; week 3, 2,400 mg; and week 4, 3,600 mg) and a 4-week fixed-dose period wherein the dose that was effective and tolerable from the titration phase was held constant. There were no differences in demographics or rates of dropout because of inefficacy or adverse events between the gabapentin group and the placebo group.

Among the 229 postherpetic neuralgia patients (Rowbotham et al. 1998), greater pain reduction occurred with gabapentin, noted as early as week 2 and maintained throughout the entire study period. Similarly, secondary measures of mood such as depression, anger–hostility, fatigue–inertia, and physical functioning were more effectively treated with gabapentin than with placebo. Eighty-three percent of the gabapentin group was maintained on the 2,400-mg daily dose, and 65% were maintained on the 3,600-mg daily dose.

Among the 165 diabetic neuropathy patients (Backonja et al. 1998), greater pain reduction (as measured with an 11-point Likert scale) occurred with gabapentin than with placebo; this difference

was statistically significant as early as week 2 of the blind titration phase and remained significant for the duration of the 8-week study. The difference was also clinically relevant, as demonstrated by significant reductions in sleep interference related to pain and improved quality of life. Gabapentin appeared to be well tolerated, as 67% of the patient group maintained a maximum dose of 3,600 mg. The most common side effects noted with greater frequency in the gabapentin group were dizziness and somnolence.

Finally, a 7-week placebo-controlled study evaluated gabapentin (1,800 or 2,400 mg/day in three divided doses) in 334 patients with postherpetic neuralgia (Rice et al. 2001). Pain was significantly reduced with both gabapentin doses, with similar improvements in sleep. The improvement in pain score was noted as early as week 1 and was maintained throughout the study.

Movement disorders

Controlled investigations of gabapentin have been conducted in several movement disorders. These studies, albeit controlled, were much smaller than the neuropathic pain studies mentioned in the prior section but included amyotrophic lateral sclerosis (ALS) (Miller et al. 1996), essential tremor (Ondo et al. 2000; Pahwa et al. 1998), and parkinsonism (Olson et al. 1997).

In a study of 152 patients with ALS, patients were randomly assigned to a 2,400-mg daily dose of gabapentin or placebo for 6 months. Decline in muscle strength, the primary outcome measure, was slower in the gabapentin-treated patients than in the placebo-treated patients (Miller et al. 1996).

Controlled studies of gabapentin for essential tremor have reported mixed results. The first 2-week controlled study showed no difference between gabapentin 1,800 mg/day and placebo for treatment of essential tremor (Pahwa et al. 1998). A second 6-week controlled study evaluating two gabapentin dosages—1,800 mg/day and 3,600 mg/day—in patients with essential tremor found significant improvements in self-report scores, observed tremor scores, and activities of daily living scores in patients randomly assigned to gabapentin compared with patients who received placebo (Ondo et al. 2000).

In a 1-month double-blind, placebo-controlled evaluation of gabapentin in 19 patients with advanced parkinsonism, gabapentin at a mean daily total dose of 1,200 mg was superior to placebo in reducing rigidity, bradykinesia, and tremor, as measured by the United Parkinson's Disease Rating Scale (Olson et al. 1997). The authors pointed out that the rigidity and bradykinesia improvements were independent of tremor improvement.

Migraine headache

The comorbidity of migraine headache disorder and bipolar disorder is highly prevalent and clinically significant (Mahmood et al. 1999). Anticonvulsants, both for their anticonvulsant mood-stabilizing effects and for their migraine prophylactic properties, appear to be ideal in this patient population. A study by Mathew et al. (2001) suggested that gabapentin is an effective agent for migraine prophylaxis. One hundred forty-three patients with migraine (with and without aura) participated in this three-phase controlled evaluation of gabapentin. Phase 1 was a 4-week single-blind placebo period during which baseline migraine headache frequency was established. Phase 2 was a 4-week double-blind, placebo-controlled, flexible-dose titration period during which patients received gabapentin dosages of up to 2,400 mg/day. Phase 3 was an 8-week double-blind, placebo-controlled period during which the dosage of gabapentin was held constant. Patients randomly assigned to 2,400 mg/day gabapentin had significant reductions in migraine attacks in comparison with placebo-treated patients. Dropout rates were higher with gabapentin and were primarily related to drowsiness and somnolence.

Anxiety Disorders

Gabapentin has been shown in a number of animal models to exhibit a dose-dependent anxiolytic response (Singh et al. 1996). Open-trial investigations have reported positive results with add-on gabapentin in the treatment of generalized anxiety disorder (Pollack et al. 1998), panic disorder (Pollack et al. 1998), and refractory obsessive-compulsive disorder (Cora-Locatelli et al. 1998). Two controlled investigations of gabapentin in social phobia (Pande et al. 1999) and panic disorder (Pande et al. 2000b) suggest anxiolytic activity.

Pande et al. (1999) investigated gabapentin in a 14-week randomized, double-blind, placebo-controlled two-site study of 69 outpatients with DSM-IV (American Psychiatric Association 1994)–confirmed social phobia. All patients were required to have a score of 50 or higher on the Liebowitz Social Anxiety Scale (LSAS) at baseline. Reduction in the LSAS score served as the primary outcome measure. In the 69 patients randomly assigned to the intent-to-treat analysis, gabapentin was more effective than placebo in reducing social anxiety symptoms. The dosage range for gabapentin was 900–3,600 mg/day, with 56% of patients responding to and tolerating the maximum daily dosage of 3,600 mg. Dizziness and dry mouth were significantly more common in patients treated with gabapentin.

The second study was an 8-week randomized, placebo-controlled six-site monotherapy study of 103 patients with DSM-IV–confirmed panic disorder with or without agoraphobia (Pande et al. 2000b). Subjects had been experiencing at least one panic attack per week for 3 weeks prior to study entry. Gabapentin was dosed flexibly between 600 and 3,600 mg/day. The primary outcome measure was a decrease in the Panic and Agoraphobia Scale (PAS) score. The two groups had no differences in demographic profile or dropout rate. In the intent-to-treat analysis, no difference in PAS score reduction was seen between patients randomly assigned to gabapentin and those given placebo. In a post hoc stratification between high (20) and low (20) PAS symptom severity, patients with high symptom severity randomly assigned to gabapentin had a greater baseline-to-endpoint decrease in the PAS score than did those randomly assigned to placebo. Somnolence, headache, dizziness, infection, asthenia, and ataxia were more common in gabapentin-treated patients.

Bipolar Disorder

Given the demonstrated role of the FDA-approved anticonvulsants in the treatment of bipolar disorder, it was inevitable that there should be interest in evaluating gabapentin's utility as a mood stabilizer. Numerous case reports and open trials, encompassing more than 400 patients with a pooled response rate between 65% and 70%, have been reviewed elsewhere (Frye et al. 2000; Yatham et al. 2002).

One double-blind, placebo-controlled outpatient study evaluated add-on gabapentin for the treatment of bipolar I disorder with manic, hypomanic, or mixed symptoms (Pande et al. 2000a). The first phase of the study involved a 2-week single-blind, placebo lead-in wherein doses of the subject's primary mood stabilizer (lithium or valproate) could be adjusted to maximal clinical benefit and minimum threshold of therapeutic level (i.e., lithium level of 0.5 mmol/L, valproate level 50 μg/mL). The second phase of the study was a 10-week double-blind phase in which subjects were randomly assigned to either gabapentin, dosed flexibly between 600 and 3,600 mg/day (three-times-a-day dosing) or placebo. In the intent-to-treat population, 117 subjects were randomized; no differences in demographic profile or dropout rate were found between the two groups. The primary outcome measure—total decreased score on the Young Mania Rating Scale—was significantly different between groups in favor of add-on placebo. In a post hoc analysis, lithium adjustments in the single-blind, placebo lead-in phase were made more frequently in the placebo group than in the gabapentin group; most of these adjustments (9 of 12; 75%) consisted of a dosage increase. This fact suggests either a strong placebo response or the effect of maximizing lithium blood levels to achieve a greater antimanic response. Of the gabapentin-treated patients who had drug levels measured, nearly 20% had plasma gabapentin levels that were undetectable.

The second controlled study was a 6-week double-blind, placebo-controlled crossover comparative trial of gabapentin monotherapy, lamotrigine monotherapy, and placebo in 35 inpatients with refractory mood disorder (Frye et al. 2000; Obrocea et al. 2002). The primary outcome measure was a score of very much or much improved on the Clinical Global Impressions Scale; in the preliminary analysis (Frye et al. 2000) and final analysis (Obrocea et al. 2002), gabapentin demonstrated no better treatment response than placebo in a group of patients with highly refractory bipolar (primarily rapid-cycling) disorder.

There appears to be a marked contrast between the pooled results of the uncontrolled observations (generally positive) and the results of the controlled studies (generally negative). The important limitations of the controlled investigations include placebo response versus maximizing lithium response in the placebo group, lack of rigorous compliance assessment, and a monotherapy study design in a cohort of patients with primarily rapid-cycling, treatment-refractory illness.

Substance Abuse and Withdrawal

Although benzodiazepines remain the gold standard for alcohol withdrawal, mood-stabilizing anticonvulsants such as divalproex sodium and carbamazepine are clearly alternatives and possibly preferred treatments for alcohol-abusing bipolar patients (Malcolm et al. 2001). Gabapentin has been shown to decrease excitability and convulsions in animal models of alcohol withdrawal (Watson et al. 1997). The lack of hepatic metabolism, CYP enzyme induction, protein binding, or addictive potential makes gabapentin a potentially useful compound in this patient population.

The potential of gabapentin for treating alcohol withdrawal was considered after initial positive reports emerged (Bozikas et al. 2002). One study demonstrated a similar efficacy to phenobarbital in treating alcohol withdrawal (Mariani et al. 2006), although another controlled trial did not substantiate gabapentin's benefit over placebo (Bonnet et al. 2003). This latter study involved 61 inpatients admitted for a 1-week alcohol detoxification and randomly assigned to gabapentin (400 mg four times daily) or placebo. The primary outcome measure was the amount of rescue medication (clomethiazole; 1 capsule = 192 mg) required during the first 24 hours (6.2 capsules for gabapentin and 6.1 capsules for placebo). In a post hoc analysis (Bonnet et al. 2007), there was a significant increase in the Profile of Mood States (POMS) vigor subscore in the gabapentin group versus the placebo group; this was particularly robust in patients with comorbid mild depression.

Despite the conflicting results for gabapentin's efficacy in alcohol withdrawal, there is increasing recognition of its therapeutic benefit for the sleep disturbance component of alcohol withdrawal syndrome. Low-dose gabapentin (mean dose = 900 mg) in the treatment of alcohol withdrawal, in comparison with trazodone, was associated with greater improvement in sleep problems, as assessed with the Sleep Problems Questionnaire (Karam-Hage and Brower 2003). As well, in patients with a history of multiple previous alcohol withdrawals, gabapentin, in comparison with lorazepam, was associated with significant reductions in self-report sleep disturbances and daytime sleepiness (Malcolm et al. 2007).

One 4-week placebo-controlled, randomized, double-blind study evaluated gabapentin in alcohol abuse relapse prevention (Furieri and Nakamura-Palacios 2007). After detoxification, 60 alcohol-dependent men who had been consuming, on average, 17 drinks per day for the preceding 3 months were randomly assigned to gabapentin (300 mg twice daily) or placebo. The gabapentin group showed a significant reduction in both the number of drinks per day and the percentage of heavy drinking days. In addition to an increase in the percentage of days abstinent, the gabapentin group reported a significant reduction in craving for alcohol, specifically automaticity of drinking.

Side Effects and Toxicology

Gabapentin has a highly desirable side-effect profile that has been remarkably consistent among the

controlled studies of diverse disease states. Sedation, drowsiness, and dizziness always have been reported, and ataxia, dry mouth, infection, and asthenia have been reported in at least one placebo-controlled study.

Adverse events caused by gabapentin have been few but have important psychiatric implications. Gabapentin-induced hypomania and mania have been reported (Leweke et al. 1999; Short and Cooke 1995). The controlled mania study did not report data on percentage of the patients with exacerbation of mania secondary to gabapentin treatment (Pande et al. 2000a). Gabapentin also has been associated with aggression, both in pediatric epilepsy (Wolf et al. 1996) and in adult mania (Pinninti and Mahajan 2001).

Gabapentin has a broad therapeutic index and appears to be safe in overdose. The broadness of the therapeutic index is most likely related to its nonlinear bioavailability secondary to a saturable transport carrier (McLean 1999).

Drug–Drug Interactions

Given its lack of hepatic metabolism, CYP autoinduction, and minimal plasma protein binding, gabapentin has been shown not to affect levels of anticonvulsant drugs; similarly, gabapentin pharmacokinetics were unchanged with hepatically metabolized anticonvulsants ("Neurontin" 2006). Gabapentin's renal excretion, however, does pose potential risk when the drug is used concomitantly with lithium.

Although the therapeutic index with gabapentin is large, that is not the case with lithium. In a single 600-mg lithium dose pharmacokinetic study, there was no difference in maximal lithium concentration (Li C_{max}), time to reach C_{max}, or area under the curve in 13 patients receiving steady-state gabapentin (mean dose = 3,645.15 ± 931.5 mg) compared with those receiving steady-state placebo (Frye et al. 1998). It is important to emphasize that this study was in a patient population with normal renal function; cases of reversible renal impairment associated with gabapentin have been reported (Grunze et al. 1998).

Summary for Gabapentin

Controlled studies of gabapentin clearly have suggested its efficacy in several medical conditions, including complex partial epilepsy, postherpetic neuropathy, diabetic neuropathy, and migraine prophylaxis. Conclusions are less clear, either because of positive controlled studies of a small sample size or because of negative studies in alcohol abuse/dependence relapse prevention, ALS, essential tremor, parkinsonism, social phobia, and panic disorder. Gabapentin's role as a mood stabilizer is not clearly established. Gabapentin has a favorable pharmacokinetic profile, with particular advantage in patients with compromised hepatic function. Its minimal drug–drug interactions, low risk of toxicity, and favorable side-effect profile make it a useful addition to the pharmacopoeia.

PREGABALIN

Pregabalin is an anticonvulsant drug approved by the FDA for the adjunctive treatment of partial-onset seizures in adults. It is also approved for the treatment of neuropathic pain associated with diabetic peripheral neuropathy, postherpetic neuralgia, and fibromyalgia. Like many of the newer anticonvulsant agents, pregabalin has been evaluated in carefully controlled studies for possible utility in neurological and psychiatric conditions other than primary epilepsy.

Pharmacological Profile and Mechanism of Action

Pregabalin, like gabapentin, is a structural analog of the inhibitory neurotransmitter GABA. Pregabalin has shown greater potency than gabapentin in preclinical models of epilepsy, pain, and anxiety (Hamandi and Sander 2006). Although pregabalin is a GABA structural analog, it has no clinically significant effect at either the $GABA_A$ or $GABA_B$ receptor and is not converted metabolically into GABA

or a GABA agonist (Kavoussi 2006). Furthermore, pregabalin does not bind to any serotonergic, dopaminergic, or glutamatergic receptors. It is known that pregabalin does bind to the $\alpha_2\delta$ subunit of the presynaptic voltage-gated calcium channel and that this binding results in a decrease in excitatory neurotransmitter release (Dooley et al. 2002; Kavoussi 2006). In contrast to other GABA reuptake inhibitory anticonvulsants (e.g., tiagabine) or anticonvulsants that modulate enzymatic activity related to GABA production (e.g., vigabatrin), pregabalin does not have any direct GABA reuptake–inhibitory effects or GABA transaminase–inhibiting effects.

Pharmacokinetics and Disposition

Pregabalin exhibits linear pharmacokinetics. Pregabalin is not associated with any significant protein binding or hepatic metabolism. Pregabalin oral bioavailability is greater than 90% and independent of dose. Steady-state plasma levels are generally achieved within 24–48 hours. Administration with food has no clinically significant effect on the extent of absorption or on elimination. The elimination half-life of the drug is approximately 6.5 hours (Montgomery 2006). Pregabalin is highly lipophilic and does not bind to plasma protein and, therefore, readily crosses the blood–brain barrier. Pregabalin is primarily renally excreted. There are no active metabolites. Pregabalin does not induce or inhibit CYP enzymes, nor do CYP enzyme inhibitors alter its pharmacokinetics as a consequence. Because of its renal elimination, dosage adjustment is required in patients with renal impairment.

Indications and Efficacy

Epilepsy

Several placebo-controlled studies have evaluated pregabalin in the treatment of patients with refractory partial epilepsy (Elger et al. 2005; Hamandi and Sander 2006). Response rates for pregabalin dosed at 600 mg/day were similar to those reported in other trials of antiepileptic drugs in refractory epilepsy. The study by Elger et al. (2005) showed that pregabalin administered in either fixed or flexible doses was highly effective and generally well tolerated as add-on therapy for partial seizures with or without secondary generalization.

Nonepilepsy Neurological Conditions

Postherpetic neuralgia

Four placebo-controlled studies have evaluated pregabalin for postherpetic neuropathic pain (Dworkin et al. 2003; Freynhagen et al. 2005; Sabatowski et al. 2004; Van Seventer et al. 2006). The first study (Dworkin et al. 2003) was an 8-week parallel-group, double-blind, placebo-controlled, randomized multicenter trial of patients with postherpetic neuralgia, who received either pregabalin 600 mg/day (300 mg/day if reduced creatinine clearance) or placebo. The primary efficacy measure was mean pain ratings using an 11-point numerical pain rating scale kept in a daily diary. At study endpoint, there was a significant decrease in mean pain scores for patients treated with pregabalin compared with placebo. The superior pain relief with pregabalin was identified as early as day 2 and was maintained throughout the 8 weeks of double-blind treatment. In a second study (Freynhagen et al. 2005), patients with chronic postherpetic neuralgia or diabetic peripheral neuropathy were randomly assigned to placebo, flexible-dose pregabalin titrated upward to a maximum dosage of 600 mg/day, or fixed-dose pregabalin at 300 mg/day for the first week followed by 600 mg/day for the remaining 11 weeks. Both flexible- and fixed-dose pregabalin significantly reduced endpoint mean pain scores and were significantly superior to placebo in improving pain-related sleep interference. In a third study, Van Seventer et al. (2006) evaluated pregabalin (150, 300, or 600 mg/day in bid dosing) or placebo in 370 patients with postherpetic neuralgia. Pregabalin provided significant dose-proportional pain relief at endpoint, different from placebo. Sleep interference in all pregabalin groups was significantly improved at endpoint. Similar results were obtained in the Sabatowski et al. (2004)

study, which reported improvement in sleep and mood disturbance in patients treated with pregabalin. In total, these four studies showed benefit in pain reduction, sleep improvement, and mood associated with pregabalin treatment. The most common side effects were dizziness, peripheral edema, weight gain, and somnolence. The pain-reduction benefits, in comparison with placebo, were noted early in the clinical trial and were sustained for the duration of the study.

Diabetic peripheral neuropathy

Freeman et al. (2008) conducted a pooled analysis of data from seven published randomized, placebo-controlled trials encompassing 400 patients with diabetic peripheral neuropathy. The primary outcome measure was change from baseline to endpoint in mean pain score from patients' daily pain diaries. With three-times-daily administration, all pregabalin dosages (150, 300, and 600-mg/day) significantly reduced pain and pain-related sleep interference in comparison with placebo. With twice-daily administration, only the 600-mg/day dosage showed efficacy. Pregabalin's pain-reducing and sleep-improving properties appeared to be positively correlated with dose, with the greatest effect observed in patients treated with 600 mg/day.

Fibromyalgia

Pregabalin is the first medication to receive an FDA indication for the treatment of fibromyalgia. Fibromyalgia is a common chronic pain disorder characterized by widespread diffuse musculoskeletal pain and tenderness frequently accompanied by significant psychiatric comorbidity, including fatigue, sleep disturbance, and mood and anxiety disorders. Classifications of disease severity for fibromyalgia have been published by the American College of Rheumatology (Wolfe et al. 1990). Prevalence estimates for fibromyalgia are 2% of the U.S. population, with rates higher in adult women than in men (Arnold et al. 2007).

Two placebo-controlled acute-treatment studies (Crofford et al. 2005; Mease et al. 2008) and one placebo-controlled relapse prevention study (Crofford et al. 2008) have evaluated pregabalin in the treatment of patients with fibromyalgia. In the first, an 8-week double-blind, randomized, placebo-controlled study of pregabalin (150, 300, and 450 mg/day) versus placebo, the 450-mg daily dose significantly reduced the average severity of pain in comparison with placebo (Crofford et al. 2005). Sleep improvement was noted at both the 300- and the 450-mg daily dosages. Dizziness and somnolence were the most frequent adverse events. Arnold et al. (2007), in recognition of the large overlap of psychiatric comorbidity in fibromyalgia, conducted a post hoc analysis of the Crofford et al. (2005) study to assess symptoms of anxiety and depression and their impact on pregabalin treatment. Of 529 patients who had enrolled in pregabalin treatment for fibromyalgia, significantly more patients endorsed anxiety symptoms (71%) than endorsed depressive symptoms (56%). Improvement in pain symptoms with pregabalin versus placebo did not depend on baseline anxiety or depression; in fact, 75% of the pain reduction was not explained by improvements in mood and/or anxiety.

The second 13-week double-blind, placebo-controlled multicenter study randomly assigned 748 patients with fibromyalgia to receive either placebo or pregabalin dosages of 300, 450, or 600 mg/day (twice-daily dosing) (Mease et al. 2008). The primary outcome measure was symptomatic relief of pain associated with fibromyalgia, as measured by a mean pain score from an 11-point numeric rating scale (0 = no pain; 10 = worst possible pain) from patients' daily diaries. Patients in all pregabalin groups showed statistically significant improvement in endpoint mean pain score. Compared with the placebo group, all pregabalin treatment groups showed statistically significant improvement in sleep.

Finally, the FREEDOM (Fibromyalgia Relapse Evaluation and Efficacy for Durability Of Meaningful relief) study evaluated pregabalin in a 6-month double-blind, placebo-controlled design (Crofford et al. 2008). This study included an initial 6-week open-label phase followed by a 26-week double-blind treatment with ongoing pregabalin or blind substitution to placebo. The primary outcome measure was time to loss of therapeutic response, defined as a less than 30% reduction in pain or worsening of

symptoms of fibromyalgia. More than 1,000 patients entered the open-label phase, with 287 being randomly assigned to placebo and 279 to pregabalin. Time to loss of therapeutic response was significantly greater for the pregabalin group than for the placebo group, with Kaplan-Meier estimates of time to event showing that half of the placebo group had relapsed by day 19, whereas half of the pregabalin group had still not lost response by trial end. At the end of the double-blind phase, 61% of the placebo-treated patients had lost therapeutic response, compared with only 32% of the pregabalin-treated patients.

These three placebo-controlled studies in the acute or relapse prevention phase in patients with fibromyalgia mark a substantial advance in clinical trial design of novel uses of anticonvulsants and represent a milestone in the first FDA-approved treatment for fibromyalgia.

Anxiety Disorders

Generalized anxiety disorder

Four placebo-controlled studies have evaluated pregabalin in generalized anxiety disorder (Montgomery et al. 2006; Pande et al. 2003; Pohl et al. 2005; Rickels et al. 2005). In the first study (Pande et al. 2003), 276 patients with generalized anxiety disorder were randomly assigned to pregabalin 150 or 600 mg/day, lorazepam 6 mg/day, or placebo. The 6-week trial included a 1-week placebo lead-in, 4 weeks of blind treatment, and a 1-week taper. The primary efficacy outcome measure was the endpoint Hamilton Anxiety Scale (Ham-A) score. The mean baseline-to-endpoint decrease in Ham-A total score in all three active-treatment groups (pregabalin 150 mg/day, pregabalin 600 mg/day, and lorazepam 6 mg/day) was significantly greater than the decrease in the placebo group. Percentages of subjects who met a secondary outcome measure, a reduction of 50% or greater in the Ham-A score, were significantly higher in the pregabalin 600-mg/day group (46%) and the lorazepam group (61%) than in the placebo group (27%). There were no significant differences in response rates by either definition between patients receiving pregabalin 150 mg/day and patients receiving placebo.

In the second study by Pohl et al. (2005), twice-daily versus three-times-daily dosing of pregabalin was evaluated in a 6-week double-blind, placebo-controlled study. In this study, 250 patients with generalized anxiety disorder were randomly assigned to pregabalin 100 mg twice daily, 200 mg twice daily, 150 mg three times daily, or placebo. Mean improvement in the Ham-A total score was significantly greater with pregabalin at all doses than with placebo. Pairwise comparisons of twice-daily versus three-times-daily dosing found no significant differences in outcome. All three pregabalin groups showed significantly greater improvement in comparison with placebo at endpoint.

In the third study by Rickels et al. (2005), 454 patients with generalized anxiety disorder were randomly assigned in a 4-week design to pregabalin 300 mg/day, 450 mg/day, or 600 mg/day; alprazolam 1.5 mg/day; or placebo. The primary outcome measure was change from baseline to endpoint in the total Ham-A score. In comparison with the placebo group, all treatment groups showed significantly greater reductions in mean Ham-A total score at last-observation-carried-forward (LOCF) analysis. A significantly higher proportion of patients in the pregabalin (all dosages) and alprazolam groups than in the placebo group met the endpoint response criterion of 50% or greater reduction in Ham-A total score. The response rate for the 300-mg/day pregabalin group (61%) was significantly higher than that for the alprazolam group (43%).

In the only pregabalin study with an active antidepressant comparator, Montgomery et al. (2006) randomly assigned 421 patients with generalized anxiety disorder to 6 weeks of double-blind treatment with pregabalin (400 or 600 mg/day), venlafaxine (75 mg/day), or placebo. The primary outcome measure was change in the Ham-A total score from baseline to LOCF analysis. Pregabalin (both dosages) and venlafaxine produced significantly greater improvement in the Ham-A total score

than did placebo. Patients receiving pregabalin 400 mg/day experienced significant improvement in all primary and secondary outcome measures in comparison with those receiving placebo. Rates of discontinuation associated with adverse events were highest in the venlafaxine group (20.4%), followed by the pregabalin 600 mg/day (13.6%), pregabalin 400 mg/day (6.2%), and placebo (9.9%) groups. These studies, taken together, contributed to the approval of pregabalin in Europe for generalized anxiety disorder.

Social anxiety disorder

In the one study by Pande et al. (2004), 135 patients with social anxiety disorder were randomly assigned to 10 weeks of double-blind treatment with either pregabalin (low dose: 150 mg/day; high dose: 600 mg/day) or placebo. The primary outcome measure was change from baseline to endpoint in the LSAS total score. Patients randomly assigned to pregabalin 600 mg/day showed significant decreases in LSAS total score compared with those receiving placebo. Significant differences between high-dose pregabalin and placebo were also noted on several secondary measures, including the LSAS subscales total fear, avoidance, social fear, and social avoidance. Low-dose pregabalin (150 mg/day) was not significantly better than placebo. Somnolence and dizziness were the most frequently reported adverse events.

Substance Abuse and Withdrawal

As previously noted, pregabalin has no hepatic metabolism and is excreted essentially unchanged in the urine. This pharmacokinetic profile is ideal for patients with alcohol abuse or dependence who have elevated transaminases but need safe, efficacious treatment for symptoms of alcohol withdrawal. One preclinical study highlighted the potential use of pregabalin and its anticonvulsant, analgesic, anxiolytic properties in a mouse model of alcohol dependence (Becker et al. 2006). Controlled clinical studies of pregabalin in alcohol-dependent patients are encouraged.

Side Effects and Toxicology

In general, the side effects commonly occurring with pregabalin treatment have been mild and not associated with a severity sufficient to warrant drug discontinuation. The most frequently reported symptoms have been dizziness, sedation, dry mouth, edema, blurred vision, weight gain, and concentration difficulty. In controlled clinical trials with pregabalin, significant weight gain (a gain of 7% or more over baseline) was observed in 9% of patients treated with pregabalin, compared with 2% of patients treated with placebo. Pregabalin treatment does not appear to be associated with significant changes in heart rate, blood pressure, respirations, or electrocardiogram measures. Peripheral edema has occurred in a small percentage of patients, but only in rare circumstances has it been identified as severe.

Available preclinical and clinical data suggest that pregabalin has very low abuse liability and is unlikely to produce significant physical dependence. There have been postmarketing reports of angioedema and hypersensitivity in patients treated with pregabalin (Pfizer 2006).

Drug–Drug Interactions

Pregabalin does not induce or inhibit CYP enzymes, nor do CYP enzyme inhibitors alter its pharmacokinetics as a consequence. Therefore, hepatic and CYP drug–drug interactions are not relevant when pregabalin is part of a complex polypharmacotherapy regimen. Because of the drug's renal elimination, dosage adjustment is required for patients with renal impairment. To date, no pharmacokinetic drug–drug interactions have been identified. There is some literature to suggest that there can be an additive cognitive impairment when pregabalin is taken in conjunction with oxycodone and that pregabalin may potentiate the effects of lorazepam and alcohol (Pfizer 2006).

Summary for Pregabalin

Controlled studies of pregabalin clearly have suggested its efficacy in complex partial epilepsy, postherpetic neuropathy, diabetic neuropathy, fibromyalgia, generalized anxiety disorder, and social anxiety disorder. Like gabapentin, pregabalin has a favorable pharmacokinetic profile, with particular advantages in patients with compromised hepatic function. Its minimal drug–drug interactions, low risk of toxicity, and favorable side-effect profile make it a useful addition to the pharmacopoeia.

CONCLUSION

There is increasing interest in the use of anticonvulsant drugs in mood and anxiety disorders. Controlled studies are needed to further assess specific patient populations and disease states that can benefit from these agents.

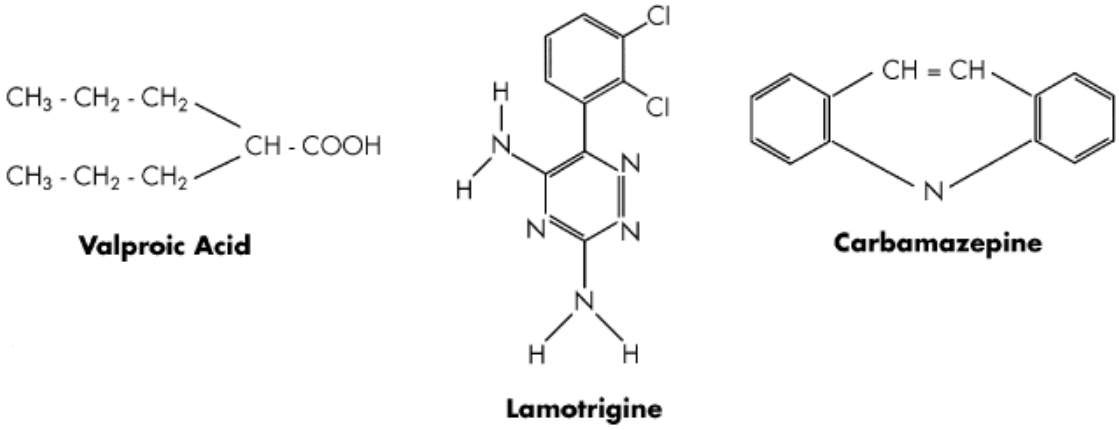
Chapter 39. Lamotrigine

HISTORY AND DISCOVERY



The initial premise in evaluating lamotrigine as an anticonvulsant was that it might possess sufficient dihydrofolate reductase inhibition to decrease folate activity, a mechanism known to reduce epileptic effects. Although its antifolate properties were only modest, anticonvulsant effects were significant. During the clinical development of lamotrigine as a treatment for intractable seizures, improved mood in lamotrigine-treated patients was anecdotally reported (Jawad et al. 1989; Smith et al. 1993). Indeed, antiepileptic drugs (AEDs) have been described as a heterogeneous class of medications with a diverse range of utility in psychiatry with variable effects on mood (Muzina et al. 2005).

In 1993, Smith et al. evaluated mood state and quality of life among patients taking AEDs. Using a crossover design, the investigators administered add-on lamotrigine to 81 epileptic patients who were already receiving either enzyme-inducing AEDs (*n* = 56) or both enzyme inducers and valproate (*n* = 25). The principal variable of interest was seizure frequency; among the secondary response variables were subjective reports of anxiety, depression, self-esteem, mastery, and happiness. Although no difference was found in the levels of depression reported by patients receiving lamotrigine and those receiving placebo, lamotrigine-treated patients reported significantly higher levels of happiness on the Affect Balance Scale (Bradburn 1969) and an improvement in perceived internal locus of control according to a self-reported mastery scale (Pearlin and Schooler 1978). There was no correlation between perceived happiness and changes in seizure frequency or severity. Thus, the investigators concluded that lamotrigine has an effect on mood independent of its antiepileptic effect (Smith et al. 1993).

STRUCTURE–ACTIVITY RELATIONS

Lamotrigine (3,5-diamino-6-[2,3-dichlorophenyl]-1,2,4-triazine, $C_9H_7Cl_2N_5$) is an AED of the phenyltriazine class that is chemically unrelated to hepatic enzyme inducers (e.g., carbamazepine) and enzyme inhibitors (e.g., valproic acid) (Figure 39–1). The reduction of dihydrofolate to tetrahydrofolate via inhibition of dihydrofolate reductase may result in the inhibition of nucleic acid and protein synthesis, secondary disruption of neural structure and function, and tertiary disruption of mood. However, as noted above, the correlation between inhibition of folic acid production and antiepileptic activity was found to be low, so the structure–activity relationship of lamotrigine with respect to antiseizure activity is unknown. Similarly, there are no published data clearly linking the structure of lamotrigine to its empirical mood-stabilizing properties.

PHARMACOLOGICAL PROFILE

Lamotrigine has not been shown to inhibit the reuptake of norepinephrine, dopamine, or serotonin. Although it exerts inhibitory effects at the serotonin$_3$ (5-HT$_3$) receptor, this activity is weak and unlikely to contribute to its therapeutic profile. Lamotrigine does not exhibit high binding affinity to adrenergic (α_1, α_2, β), dopamine (D_1, D_2), γ-aminobutyric acid (GABA), histamine (H_1), opioid (κ or θ), or muscarinic (M_1, M_2) acetylcholine receptors. Like phenytoin, lamotrigine inhibits use-dependent Na^+ channels, allowing continued normal depolarizations but suppressing paroxysmal burst firing encountered in seizures and hypoxic insult. It exhibits neuroprotective effects through inhibiting glutamate release secondary to ischemia, but it does not inhibit *N*-methyl-D-aspartate (NMDA)–induced depolarizations.

PHARMACOKINETICS AND DISPOSITION

Oral lamotrigine is rapidly absorbed with negligible first-pass metabolism. Peak plasma concentrations are reached in approximately 2–4 hours, and its half-life is approximately 25 hours (GlaxoSmithKline 2007). Bioavailability is not altered by food, and the chewable tablets are equivalent in the rate and extent of absorption as compared to the compressed tablets. Lamotrigine is approximately 55% bound to plasma proteins and is unlikely to significantly interact with drugs that are highly protein bound. Metabolism is primarily achieved by competitive glucuronic acid conjugation. The principal product is an inactive lamotrigine-2-*N*-glucuronide conjugate, found predominantly in urine and to a lesser extent in feces. Ten percent of lamotrigine is excreted unchanged. At steady-state concentrations, the pharmacokinetics of lamotrigine are linear within a dosage range of 100–700 mg/day (Leach et al. 1995). The clearance of lamotrigine is reduced in the setting of renal insufficiency and hepatic disease. Race also appears to affect the clearance of lamotrigine, with rates 25% lower in nonwhites than in whites.

There is growing awareness that perturbations in lamotrigine levels occur during pregnancy. Ohman et al. (2000) first reported data from nine pregnant epileptic women, revealing marked elevations in maternal plasma lamotrigine levels during the first 2 weeks postpartum. Lamotrigine levels increased by as much as 170% from levels taken at the time of delivery. Pennell et al. (2004) extended upon this finding in a sample of 14 women treated with lamotrigine monotherapy throughout pregnancy and during the postpartum period. The authors observed an increasing magnitude of lamotrigine clearance during each trimester, reaching a peak of 330% of baseline clearance by week 32 gestational age. Plasma levels were noted to rapidly return to normal during the first few postpartum weeks. The increase in clearance during pregnancy presumably reflects an increase in gonadal steroid production (Pennell 2003) and primary metabolism through hepatic glucuronidation.

In newborns of mothers receiving lamotrigine, extensive placental transfer of drug has been found to occur, with umbilical cord concentrations approaching those of maternal serum (Ohman et al. 2000). Nursing infants demonstrate plasma lamotrigine concentrations approximately 23%–50% of maternal levels. Any adverse effects to neonates that may result from lamotrigine exposure through breast-feeding are not well characterized.

MECHANISM OF ACTION

The mechanism by which lamotrigine exerts its therapeutic psychotropic effects is not clear but is presumed to be associated with its antiepileptic activity. Given this presumption, it is the use- and voltage-dependent inhibition of voltage-activated sodium channels (Xie and Hagan 1998) that best characterize lamotrigine's mechanism of action. In addition to sodium channel inhibition, lamotrigine demonstrates inhibition of glutamine-induced repetitive burst firing in cultured rat cortical neurons (Miller et al. 1986) and cultured spinal cord neurons (Cheung et al. 1992). Initial, but not subsequent, stimuli of burst-firing wavetrains are comparatively unimpeded by high-concentration lamotrigine (Cheung et al. 1992; Miller et al. 1986). This effect is attenuated by hyperpolarization. Subsequent stimuli in the wavetrains show attenuation, as evidenced by frequency-dependent inhibition of Na^+ receptor flux (Cheung et al. 1992; Lang and Wang 1991; Lang et al. 1993; Miller et al. 1986). Together, these data support the concept of lamotrigine-induced inhibition of Na^+ flux at presynaptic use- and voltage-sensitive sodium channels. The inhibition appears to be greatest in paroxysmally depolarized (rapidly firing) neurons. This is significant, because paroxysmal discharge produced by neuronally, physically, or chemically induced kindling has been generally accepted as a model of the induction and propagation of cortical seizure activity (Ayala et al. 1970). In a complementary manner, kindling has also been proposed as a potential contributor to mood cycling in bipolar disorder (Post et al. 1984). According to the kindling theory, the progression of bipolar episodes evolves from being reactive and triggered by environmental life stressors to occurring spontaneously. More worrisome, this process may contribute to a treatment-refractory course of illness (Post et al. 2001). Mechanistically, preferential attenuation of paroxysmal wavetrains could permit normal neuronal activity to continue unimpeded but still suppress seizure activity and affective instability. However, this hypothesis is limited in its ability to explain the more enduring mood-stabilizing effects that occur apart from bursts of paroxysmal electrical discharges.

In addition to inhibitory activity on sodium channels, there is also evidence for antagonistic action by lamotrigine on N-type Ca^{++} channels in rat cortical neurons and CA1/CA3 regions of guinea pig hippocampal slices (Stefani et al. 1996; von Wegerer et al. 1997). Given prior reports ascribing modest antimanic effects to calcium channel blockers, the mechanism of calcium channel blockade may also contribute to lamotrigine's thymoleptic properties (Dubovsky 1993).

Antiglutamatergic action is another means by which lamotrigine may function as a mood stabilizer. The presynaptic inhibitory effects of lamotrigine on voltage- and use-sensitive sodium channels, calcium channels, and potassium channels (Grunze et al. 1998) are believed to result in decreased release of the excitatory amino acid glutamate. In humans, support for lamotrigine's antiglutamatergic action includes an ability to reduce perceptual abnormalities induced by the NMDA receptor antagonist ketamine (Anand et al. 2000). Yet blockade of glutamate release is independent of any NMDA affinity, as lamotrigine-associated antagonism of NMDA-induced depolarizations or other NMDA-linked stimuli has not been reported in animal models (Harrison and Simmonds 1985). Lamotrigine's ability to inhibit veratrine-induced glutamate and aspartate release (Leach et al. 1986) may translate clinically into greater activation and alertness, accounting for its observed ability to stabilize mood from below baseline.

Mechanisms unlikely to account for lamotrigine's clinical efficacy in bipolar depression and ability to provide prophylaxis against recurring mood episodes include activity at GABAergic, serotonergic, and other monoaminergic receptors. Lamotrigine does not have robust monoamine oxidase inhibitor activity for either the A or B isoforms (Southam et al. 2005), nor does lamotrigine have high affinity for $GABA_A$ or $GABA_B$ receptors. At the $5\text{-}HT_3$ receptor, only weak inhibitory effects have been reported. Although there were no alterations in $5\text{-}HT_{1A}$ receptor function after 1 week of lamotrigine administration to healthy male volunteers (Shiah et al. 1998), there is preliminary evidence in animals to show that postsynaptic $5\text{-}HT_{1A}$ receptors may be affected by lamotrigine (Bourin et al. 2005). In this regard, lamotrigine appears to function more similarly to valproate and carbamazepine than to lithium. Although the mechanisms are not completely understood, support for potential neuroprotective effects of lamotrigine come from studies of rat hippocampal CA1 cells, where the agent reduced cell damage resulting from global cerebral ischemia (Crumrine et al. 1997) and decreased hippocampal neuronal loss after pretreatment with lamotrigine (Maj et al. 1998).

INDICATIONS AND EFFICACY

Lamotrigine is indicated for adjunctive antiepileptic therapy in adults with partial seizures and in patients with generalized seizures secondary to Lennox-Gastaut syndrome. The most recently approved indication is for adjunctive use in primary and generalized tonic-clonic seizures in adults and pediatric patients (≥2 years of age).

In 2003, lamotrigine became the first medication since lithium to be granted U.S. Food and Drug Administration (FDA) approval for use in the maintenance treatment of bipolar I disorder to delay the time to occurrence of new mood episodes. Olanzapine, aripiprazole, and quetiapine have subsequently received this indication for bipolar disorder.

Maintenance Therapy in Bipolar I Disorder

Two large randomized, double-blind, parallel-group, placebo-controlled multicenter studies led to the approval of lamotrigine as a maintenance therapy in bipolar I disorder (Bowden et al. 2003; Calabrese et al. 2003). Both of these paired studies included a screening phase of up to 2 weeks; an 8- to 16-week open-label phase during which lamotrigine was initiated as adjunctive or monotherapy and other psychotropic drugs were discontinued; and an 18-month double-blind phase during which patients received lamotrigine, lithium, or placebo as maintenance therapy. The primary efficacy variable in both studies was time to intervention for any mood episode.

One of the studies (Bowden et al. 2003) evaluated subjects who were or had recently been in a manic, hypomanic, or mixed state. The other study (Calabrese et al. 2003) examined subjects who were or had recently been depressed.

Both lamotrigine and lithium were significantly superior to placebo on time to intervention for any mood episode ($P = 0.018$ for previously manic; $P = 0.029$ for previously depressed). Lamotrigine-treated patients showed longer survival-in-study times than did control subjects ($P = 0.03$ for formerly manic; $P = 0.003$ for formerly depressed). Lithium-treated formerly depressed patients also showed longer survival-in-study times relative to control subjects ($P = 0.022$), and there was a nonsignificant trend for lithium-treated formerly manic patients to show longer in-study survival as well ($P = 0.07$). Lamotrigine, but not lithium, was superior to placebo at prolonging the time to a depressive episode ($P = 0.015$ for previously manic; $P = 0.047$ for previously depressed). Lithium, but not lamotrigine, was superior to placebo at prolonging the time to a manic, hypomanic, or mixed episode ($P = 0.006$ for previously manic; $P = 0.026$ for previously depressed). There was no evidence in these studies of worsening manic or depressive symptoms or of accelerated cycling frequency during lamotrigine treatment.

In contrast to both individual maintenance studies, a pooled analysis of these two clinical trials conducted by Goodwin et al. (2004) found lithium and lamotrigine to be statistically superior to placebo at prolonging the time to intervention for a manic, hypomanic, or mixed episode ($P = 0.034$ for lamotrigine vs. placebo; $P \leq 0.001$ for lithium vs. placebo). However, lamotrigine, but not lithium, remained the only compound that was statistically superior to placebo at prolonging the time to intervention for a depressive episode ($P = 0.009$ for lamotrigine vs. placebo; $P = 0.120$ for lithium vs. placebo).

In the interpretation of maintenance-phase data, it is important to distinguish between efficacy in relapse prevention and pure prophylactic efficacy (Ghaemi et al. 2004). Mood episodes of the same polarity as the index episode that occur during the initial 2 months following recovery are generally regarded as *relapses.* As such, this period is termed the acute recovery phase. Alternatively, mood episodes that occur beyond this phase during the period of remission are regarded as *recurrences.* To test the pure maintenance efficacy of lamotrigine, Calabrese et al. (2006) conducted a post hoc analysis of the two double-blind 18-month maintenance trials that compared lamotrigine and lithium against placebo. In their analysis, all subjects were excluded who experienced a relapse to a mood episode of the same polarity as the index episode within 90 or 180 days of randomization. After subjects who relapsed to a mood episode within 90 days of randomization were excluded, data were available from 167 lamotrigine-treated patients, 131 lithium-treated patients, and 133 placebo-treated patients. Lamotrigine and lithium were both more effective than placebo at delaying the time to intervention for a mood episode ($P = 0.02$ for lamotrigine; $P = 0.010$ for lithium). Similar results were found when patients who relapsed to a mood episode of the same polarity as their index episode within 180 days of randomization were excluded. When overall survival in the study until dropout for any reason was examined, only lamotrigine was significantly more effective than placebo ($P = 0.002$ for lamotrigine; $P = 0.098$ for lithium). Because these results are consistent with the primary analyses of the independent studies that included patients who potentially relapsed into their index episode, the findings indicate that lamotrigine and lithium possess true maintenance efficacy.

Acute Treatment of Bipolar Depression

Evaluation of lamotrigine's spectrum of activity was prompted by early reports of putative psychotropic efficacy in patients with epilepsy as summarized above. To replicate and extend preliminary open-label prospective findings suggesting moderate to marked efficacy in depression, hypomania, and mixed states (Calabrese et al. 1999a), a series of multicenter double-blind, placebo-controlled studies was completed. The first study in this series was conducted to evaluate the efficacy and safety of two doses of lamotrigine compared with placebo in the acute treatment of a major depressive episode in 195 patients with bipolar I disorder (Calabrese et al. 1999b). Outpatients received lamotrigine (50 or 200 mg/day) or placebo as monotherapy for 7 weeks. Psychiatric evaluations, including the Hamilton Rating Scale for Depression (Ham-D), the Montgomery-Åsberg Depression Rating Scale (MADRS), the Mania Rating Scale (MRS), and the Severity of Illness and Improvement subscales of the Clinical Global Impression Scale (CGI-S and CGI-I, respectively), were completed at 4 days and then weekly. Lamotrigine at a dosage of 200 mg/day demonstrated significant antidepressant efficacy on the MADRS, Ham-D Item 1, CGI-S, and CGI-I compared with placebo. Improvements were seen as early as week 3. Lamotrigine at a dosage of 50 mg/day approached significance compared with placebo on several efficacy measures. The proportion of patients exhibiting a marked response on the CGI I was 51%, 41%, and 26% for the lamotrigine 200 mg/day, lamotrigine 50 mg/day, and placebo groups, respectively. The rate of switching was not significantly different between lamotrigine (4.6%–5.4%) and placebo (5%) without concurrent psychotropic medication. Of 65 subjects randomly assigned to placebo, 3% cycled into hypomania, 0% into mania, and less than 1% into mixed states. Of 129 patients randomly assigned to lamotrigine, less than 1% cycled into hypomania, 3% into mania, and less than 1% into mixed states. These data suggest that lamotrigine monotherapy is an efficacious and well-tolerated treatment for bipolar depression and that the switch rate associated with the use of lamotrigine does not exceed that typically seen in the natural course of the illness.

Although there is expert consensus that lamotrigine is effective for acute bipolar depression and confirmation with one adequately powered placebo-controlled trial (Calabrese et al. 1999b), there have been four randomized, parallel-group, placebo-controlled monotherapy trials of lamotrigine that have failed to separate from placebo (Calabrese et al. 2008). These include a 10-week flexible-dose (100–400 mg) study of patients with bipolar I or II disorder, an 8-week fixed-dose (200 mg) study of patients with bipolar II disorder, and two 8-week fixed-dose (200 mg) studies of patients with bipolar I disorder. In none of the four studies were significant improvements over placebo observed on the 17- and 31-item Ham-D, MADRS, CGI-S, or CGI-I. The effect sizes of the primary and secondary endpoints for these four studies were small, suggesting that insufficient numbers of subjects may have been randomized to detect a significant treatment effect. In contrast to the study demonstrating superiority of lamotrigine over placebo in treating acute bipolar depression, the placebo response rates in these four studies were variably high.

To clarify the effects of lamotrigine in acute bipolar depression, Geddes et al. (2009) conducted a systematic meta-analysis of individual patient data from 1,072 participants in all five randomized, controlled trials comparing lamotrigine with placebo. The pooled analysis showed that more patients treated with lamotrigine than with placebo responded on both the Ham-D and the MADRS ($P = 0.002$). However, the advantage over placebo was larger in more severely depressed patients.

Rapid-Cycling Bipolar Disorder

Calabrese et al. (2000) conducted a large study in rapid-cycling bipolar disorder consisting of two phases: an 8- to 12-week open-label preliminary phase and a 26-week randomized phase. Subjects who met criteria for mood stabilization at the end of the preliminary phase were stratified for type I and II bipolar disorder and then randomly assigned to flexible-dose lamotrigine (100–500 mg/day) or placebo to compare the efficacy of lamotrigine monotherapy with that of placebo in preventing mood episodes and to evaluate the safety of lamotrigine in this population. Three hundred twenty-six subjects were enrolled into the preliminary phase, and 182 subjects were randomly assigned to receive placebo ($n = 89$) or lamotrigine ($n = 93$). The difference between the treatment groups in time to additional pharmacotherapy for a developing or fully developed mood episode did not achieve statistical significance. However, overall survival time in the study (i.e., time to dropout for any reason) was significantly different between the treatment groups in favor of lamotrigine ($P = 0.036$). When patients with bipolar I and II subtypes were compared, lamotrigine-treated bipolar II disorder patients demonstrated a significantly longer median survival of 17 weeks compared with a median of 7 weeks for placebo-treated patients ($P = 0.015$). This study was the first long-term prospective placebo-controlled evaluation of a maintenance treatment in a large population of patients diagnosed with rapid-cycling bipolar disorder. The results suggest that lamotrigine is particularly useful for the prevention of mood episodes in bipolar II disorder. This is likely due to the predominance of depressive symptoms in bipolar II patients.

Lamotrigine Comparator Trials

To date, only two compounds are FDA approved for the treatment of acute bipolar depression: an olanzapine–fluoxetine combination (OFC) and quetiapine. To compare efficacy with an established agent for managing bipolar depression, a head-to-head randomized, double-blind, parallel-group study of lamotrigine and OFC was conducted over 7 weeks in patients with bipolar I disorder in an acute depressive phase (E. B. Brown et al. 2006). The study randomly assigned 410 subjects to either lamotrigine (titrated to 200 mg/day; $n = 205$) or OFC (6/25, 6/50, 12/25, or 12/50 mg/day; $n = 205$). Rates of response, defined as a ≥50% reduction in MADRS total score, did not differ significantly between lamotrigine (59.7%) and OFC (68.8%; $P = 0.073$). When a MADRS score of ≤12 was used to define remission, no significant differences were observed in the remission rate between lamotrigine (49.2%) and OFC (56.4%; $P = 0.181$), nor were there differences in the time to remission ($P = 0.072$). However, when improvement on the individual rating scales was compared, OFC-treated subjects showed greater decreases in the MADRS total score ($P = 0.002$) and Young Mania Rating Scale total score ($P = 0.001$) compared with lamotrigine-treated subjects. Although overall response and remission rates were comparable between the active agents, interesting differences did emerge in regard to tolerability profiles. Adverse-event rates of suicidal and self-injurious behavior were more common among patients treated with lamotrigine (3.4%) compared with OFC (0.5%; $P = 0.037$). However, significant differences in mean change from baseline to endpoint for clinically relevant laboratory results favored treatment with lamotrigine on measures such as hemoglobin A1c, prolactin, total cholesterol, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, and triglyceride levels. Importantly, the incidence of potentially clinically relevant weight gain, defined as a ≥7% increase in body weight, in OFC-treated patients was 23.4%, compared with 0% with lamotrigine ($P < 0.001$). As anticipated for a treatment trial comparing two active treatments, the effect size was modest between treatment arms (0.26).

Although lamotrigine is not indicated for the treatment of acute bipolar I depression, the similarity of its response and remission rates to those seen with OFC, an agent granted FDA approval, provide a rationale for lamotrigine's use in the acutely depressed phase of bipolar disorder, especially for patients at risk for weight gain or adverse metabolic effects. One explanation for the greater improvement on MADRS scores, but not overall response or remission rates, among OFC-treated patients may pertain to the tolerability profile of olanzapine. Side effects such as sedation or weight gain may be driving improvement on standardized rating scale measurements of insomnia or appetite loss, rather than a true antidepressant mechanism. This may place agents with a clean tolerability profile, such as lamotrigine, at a disadvantage.

An add-on trial comparing lamotrigine with placebo has also been conducted in the treatment of bipolar I and II depression (van der Loos et al. 2006). All patients were required to be taking lithium maintained at a therapeutic blood level (0.6–1.2 mmol/L) prior to randomization to lamotrigine ($n = 64$) or placebo ($n = 60$). Subjects were

treated for 8 weeks and assessed for response using the MADRS (primary outcome measure) and the Clinical Global Impression Scale–Bipolar Version (CGI-BP; Spearing et al. 1997). The change from baseline to endpoint on the MADRS was significantly greater in lamotrigine-treated subjects (15.38) compared with those receiving placebo (11.03; *P* = 0.024). A higher percentage of patients responded to add-on lamotrigine (51.6%) compared with placebo (31.7%; *P* = 0.030), although no difference was observed in the rate of response based on the CGI-BP (64.1% for lamotrigine vs. 48.3% for placebo; *P* = 0.103). A randomized, double-blind pilot trial has also compared lamotrigine (*n* = 10) and citalopram (*n* = 10) as an add-on to lithium, divalproex, or carbamazepine for bipolar I or II depression (Schaffer et al. 2006). MADRS scores decreased to a similar degree for patients taking citalopram (–10.6, SD = 8.6) as for patients taking lamotrigine (–5.0, SD = 10; *P* = 0.21). There was one case of adverse switch into hypomania in each treatment arm.

A summary of the 16 randomized, controlled multicenter trials involving lamotrigine in the treatment of mood disorders is represented in Table 39–1.

Alternative Clinical Applications

Case studies and open-label reports have been published supporting further investigation of lamotrigine for use in the treatment of myriad disorders and behavioral symptoms, including depersonalization disorder (Sierra et al. 2006), impulsive behavior (Daly and Fatemi 1999); Alzheimer's disease (Tekin et al. 1998), aggression in dementia (Devarajan and Dursun 2000), borderline personality disorder (Pinto and Akiskal 1998), posttraumatic stress disorder (Hertzberg et al. 1999), treatment-resistant unipolar depression (Gabriel 2006), alcohol (Rubio et al. 2006) and cocaine dependence (E. S. Brown et al. 2006) comorbid with bipolar disorder, schizoaffective disorder (Erfurth et al. 1998b), Rett syndrome (Stenbom et al. 1998), self-injurious behavior in the profoundly mentally retarded (Davanzo and King 1996), refractory schizophrenia (coadministered with clozapine [Saba et al. 2002]), and decreased consciousness with impaired cognition in severe brain injury (Showalter and Kimmel 2000).

DOSING

The recommended titration schedule for lamotrigine added to valproate in adult patients begins at 25 mg every other day for 14 days, advances to 25 mg daily for 14 days, and then increases by 50 mg daily beginning each of the fifth and sixth week of treatment, reaching a target dose of 100 mg daily (Table 39–2). Titration of adjunctive lamotrigine in the presence of an enzyme inducer begins at 50 mg daily for 14 days, advances to 100 mg daily (divided doses) for 14 days, to a target dosage of 400 mg daily (Table 39–3). There are no published data supporting greater efficacy of lamotrigine in the treatment of bipolar disorder at dosages greater than 200 mg/day. Additionally, there is no clear association between serum levels of lamotrigine and measures of affective response.

SIDE EFFECTS AND TOXICITY

In trials of epileptic patients who received adjunctive or monotherapy lamotrigine, the spectrum of reported side effects included dizziness, headache, diplopia, nausea, and ataxia (Messenheimer et al. 1998). In controlled monotherapy trials in mood disorders, lamotrigine has been associated with headache, changes in sleep habits, nausea, and dizziness (Bowden et al. 2004). Although the prevalence of rash in mood disorder randomized trials did not exceed that of placebo, rash is generally recognized as the side effect most likely to significantly complicate lamotrigine's clinical use (see "Rash" subsection below).

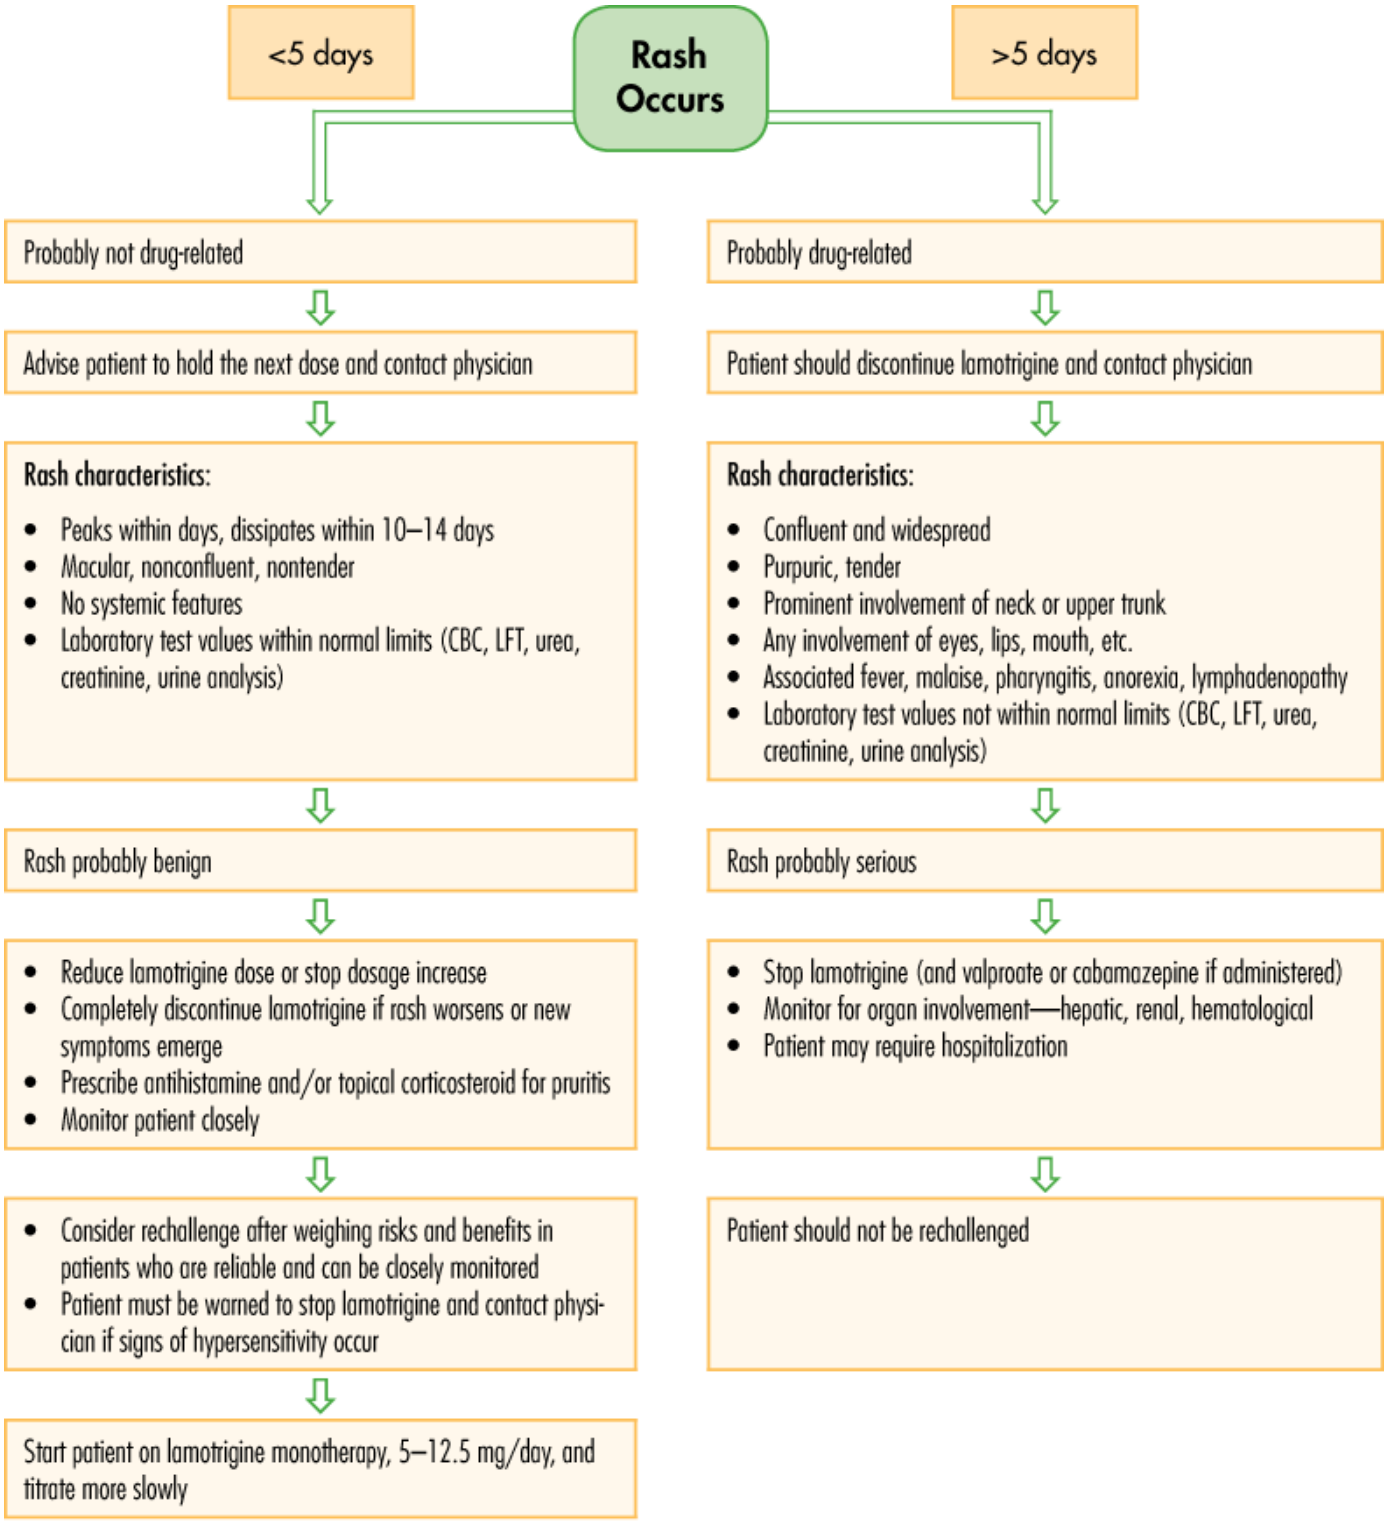
A unique feature of lamotrigine in comparison with other agents used in the management of bipolar disorder is its weight-neutral tolerability profile. Among 583 patients with bipolar disorder treated with lamotrigine, lithium, or placebo for 52 weeks, a pooled analysis showed that the percentage of patients with a greater than 7% increase in weight or change in weight did not differ between those treated with lamotrigine and those treated with lithium or placebo (Sachs et al. 2006). A higher percentage of lamotrigine-treated subjects than of lithium-treated subjects lost more than 7% of their body weight. A post hoc analysis revealed that nonobese patients taking lamotrigine are unlikely to experience a change in weight. However, obese patients are significantly more likely to lose weight with lamotrigine and to gain weight with lithium (Bowden et al. 2006).

Clinical case reports made since the release of lamotrigine have included rare associations with Tourette's syndrome (Lombroso 1999); obsessionality in the form of intrusive, repetitive phrases (Kemp et al. 2007); nephritis with colitis (Fervenza et al. 2000); eosinophilic hepatitis (Fix et al. 2006); visual loss due to cicatrizing conjunctivitis (McDonald and Favilla 2003); female sexual dysfunction (Erfurth et al. 1998a); lupus erythematosus (Sarzi-Puttini et al. 2000); stupor (Sbei and Campellone 2001); and hyponatremia in patients with diabetes insipidus (Mewasingh et al. 2000). Hypersensitivity reactions (multiorgan failure/dysfunction, hepatic abnormalities, disseminated intravascular coagulation) have also occurred with lamotrigine use.

Rash

Incidence and Prevalence

In early epilepsy trials, rash led to hospitalization and treatment discontinuation or Stevens-Johnson syndrome in 0.3% of adults treated with lamotrigine. During the controlled phase of 12 multicenter trials, no cases of serious rash occurred in lamotrigine-treated subjects (Calabrese et al. 2002). Among 1,955 patients treated with lamotrigine in an open-label setting, there was 1 case of mild Stevens-Johnson syndrome and 2 cases of serious rash. Both cases of serious rash resolved uneventfully upon lamotrigine discontinuation, with one case requiring additional treatment with oral steroids.



The annual incidence of serious drug-based skin reactions associated with lamotrigine was highest in 1993 (4.2%) but steadily declined and had stabilized by 1998 (0.02%). This is likely attributable to the manufacturer's dosage revision in 1994, which advised a more protracted titration schedule (Calabrese et al. 2002; Messenheimer et al. 1998). It is well documented that the risk of rash is heightened in children younger than 12 years, by the coadministration of valproic acid, or by exceeding the recommended initial dosage or rate of dosage escalation of lamotrigine.

Clinical Management

The most common lamotrigine-associated rash is an exanthematic maculopapular or morbilliform eruption that is benign. However, a clinically similar eruption may be associated with more rare and serious systemic hypersensitivity reactions (Guberman et al. 1999). Thus, all patients who develop a rash during the first few months of lamotrigine therapy should be instructed to hold the next dose and immediately seek medical consultation. The greatest risk of rash appears to be during the first 8 weeks of treatment. A rash during the first 5 days of therapy is usually due to a nondrug cause.

Figure 39–2 presents a decision-making algorithm for the management of benign and serious rashes. A serious lamotrigine rash is usually confluent with prominent facial and neck involvement. The rash may be tender or have a purpuric or hemorrhagic appearance. It is accompanied or preceded by fever, malaise, pharyngitis, anorexia, or lymphadenopathy (Guberman et al. 1999). Rashes with any feature(s) suggestive of a serious reaction necessitate immediate drug cessation, followed by monitoring for hepatic, renal, and hematological involvement. Tavernor et al. (1995) reported successfully restarting patients on lamotrigine after mild isolated rash; however, re-titration should progress slowly and begin at 5–12.5 mg/day. Patients should not be rechallenged if they have had a serious rash, such as a reaction associated with systemic symptoms or internal toxicity (Besag et al. 2000). Because immune tolerance to lamotrigine is lost following interruption of dosage for more than 1 week, patients should be instructed to resume lamotrigine at the prior initial start-up dose and gradually titrate upwards whenever therapy has been interrupted for more than a few days.

To explore whether the incidence of dermatological reactions could be mitigated by adherence to a series of dermatological precautions, Ketter et al. (2006) led an intervention study that randomly assigned patients to usual precautionary care versus dermatological precautionary care prior to initiation of lamotrigine therapy. Outpatients 13

years of age and older received 12 weeks of open-label lamotrigine and were instructed not to exceed the recommended initial dosage or dosage-escalation schedule. Those in the dermatological precautions group were instructed not to ingest new food, receive immunizations, or use new conditioners, cosmetics, soaps, detergents, or fabric softeners and to reduce exposure to poison ivy. Among 1,139 subjects enrolled into the trial, none experienced a serious rash. The incidence of nonserious rash did not differ between the usual care group (8.8%) and those advised to follow dermatological precautions (8.6%).

Attention must be drawn to the black box warning in the prescribing information, which instructs prescribers to ordinarily discontinue lamotrigine "at the first sign of rash, unless the rash is clearly not drug related" because "it is not possible to predict reliably which rashes will prove to be serious or life threatening" (GlaxoSmithKline 2007).

Overdose

Among 493 cases of lamotrigine toxicity in overdose, the majority of patients (52.1%) experienced no toxic clinical effects (Lofton and Klein-Schwartz 2004). Common symptoms included drowsiness, vomiting, nausea, ataxia, dizziness, and tachycardia. Rare cases of coma, seizures, heart conduction delay, and respiratory depression have been reported in overdose. Some ingestions of lamotrigine involving quantities up to 15 grams have been fatal.

Use During Pregnancy

Lamotrigine may represent an option for women with bipolar disorder during pregnancy due to its favorable tolerability profile and maintenance effects against bipolar depression. An observational study by Newport et al. (2008) examined risk of illness recurrence in pregnant women with stable bipolar disorder who continued lamotrigine treatment during pregnancy (n = 10) versus those who discontinued mood stabilizer therapy during pregnancy (n = 16). The risk of illness recurrence was 3.3 times lower when lamotrigine was continued (30.0% recurrence [3/10] vs. 100% recurrence [16/16] when patients discontinued mood stabilizers; P <0.0001; odds ratio = 23.2; 95% confidence interval = 1.5–366). A reduced risk of depressive recurrence, as well as of manic or hypomanic recurrence, was observed with continued lamotrigine treatment. It remains unclear, however, whether lamotrigine carries a lower risk of major teratogenic defects compared with other mood-stabilizing medications.

Potential adverse effects to the developing fetus of mothers receiving lamotrigine are beginning to emerge upon examination of data from international pregnancy registries (Cunnington and Tennis 2004; Holmes et al. 2006). As with any mood stabilizer, lamotrigine use during pregnancy represents an inherent dilemma for clinicians and expectant mothers, who must balance the risks associated with untreated bipolar disorder with the potential for occurrence of major congenital malformations. During treatment with valproate or carbamazepine, neural tube defects are estimated to occur in 1%–5% of neonates after first-trimester exposure. However, the risk for malformations with newer antiepileptic drugs, including lamotrigine, is less well characterized. Preliminary data from the North American Antiepileptic Drug Pregnancy Registry suggests a possible association between first-trimester exposure to lamotrigine monotherapy and cleft lip and/or cleft palate (Holmes et al. 2006). The documented oral clefts were not part of a syndrome that included other birth defects. A total of 5 cases of oral cleft occurred among 564 pregnant women, resulting in a total prevalence of 8.9 cases per 1,000. This contrasts with 0.37 per 1,000 cases in an unexposed group, representing a 24-fold increase in risk. As this association requires confirmation from other prospectively collected registries or ongoing research, the validity of the findings are uncertain. An International Lamotrigine Registry, maintained by GlaxoSmithKline since 1992, recorded a total of 14 congenital malformations among 414 outcomes (2.9%) involving a first-trimester monotherapy exposure (Cunnington and Tennis 2004). This is similar to the background risk of 2%–3% for congenital malformations in the general population. Likewise, a more recent population-based case–control study found no evidence of increased risk for orofacial clefts relative to other malformations due to lamotrigine monotherapy (Dolk et al. 2008). Lamotrigine is listed as Pregnancy Category C in terms of teratogenic effects.

DRUG–DRUG INTERACTIONS

Lamotrigine is not known to inhibit the activity of the cytochrome P450 2D6 enzyme. However, the addition of adjunctive lamotrigine to enzyme inducers such as carbamazepine, phenytoin, primidone, and phenobarbital decreases lamotrigine plasma concentrations by approximately 40%–50% (Hahn et al. 2004). The inducing effect of oxcarbazepine is approximately half that of carbamazepine (Weintraub et al. 2005). Because lamotrigine is nearly exclusively metabolized by glucuronidation, the introduction of adjunctive valproate (an enzyme inhibitor) results in immediate and successful competition for metabolism, with resultant increases in half-life. The steady-state half-life for lamotrigine in the presence of valproate is 69.6 hours (Yau et al. 1992), compared with a multidose mean half-life of 25.4 hours with lamotrigine monotherapy (GlaxoSmithKline 2007). Mixed results have been found on the composite effect of administering lamotrigine in combination with valproate plus an enzyme-inducing antiepileptic drug. Some studies have found no difference in lamotrigine clearance from that associated with monotherapy (May et

al. 1996), while others have found the inhibitory effects of valproate to predominate, resulting in lower lamotrigine clearance (May et al. 1996; Weintraub et al. 2005).

Evidence has emerged that oral contraceptives containing estrogen have the potential to decrease serum concentrations of lamotrigine by up to 64% (Sabers et al. 2001, 2003). During the long-term treatment of bipolar disorder, use of ethinyl estradiol–containing compounds may require an increase in the maintenance dose of lamotrigine by as much as twofold over the recommended target maintenance dose. Conversely, stopping estrogen-containing oral contraceptives, including during the "pill-free" week, may increase lamotrigine levels to a clinically significant range. It appears that progestogen-only compounds do not influence lamotrigine levels, regardless of whether administered by the oral, intramuscular, subdermal, or intrauterine modes (Reimers et al. 2005). Despite the potential for increased metabolism of lamotrigine when used in combination with oral contraceptives, the manufacturer does not recommend any dosage adjustments to the initial titration schedule.

CONCLUSION

The mechanism by which lamotrigine achieves its therapeutic effect in the treatment of bipolar disorder is unknown. However, its discovery has provided investigators with a novel AED for empirical validation in the routine treatment of bipolar disorder. Although initial results from trials of lamotrigine in the treatment of mania were unfavorable, subsequent maintenance studies have provided compelling data to show that lamotrigine prevents the recurrence of mood episodes and displays antidepressant efficacy, albeit most convincingly for the prophylaxis against depression in contrast to the acute diminution of depression. Even with its ability to stabilize mood from below baseline, lamotrigine appears to have a switch rate to mania or hypomania that is similar to treatment with placebo. Lamotrigine's neutral effects on body weight and favorable side-effect profile make it appealing for use in patients with comorbid metabolic syndrome or when other treatments have resulted in poor tolerability. At present, lamotrigine remains the only AED mood stabilizer with more established efficacy in the depressed illness phase than in mania or hypomania. Future controlled investigations should determine whether lamotrigine is effective in comorbid populations, such as individuals with substance use disorders, where it may act to both stabilize mood and decrease drug consumption. Trials are also needed to explore the use of lamotrigine in combination with other mood stabilizers or atypical antipsychotics, providing insight into whether combination treatment is superior to monotherapy in preventing mood relapse and recurrence.

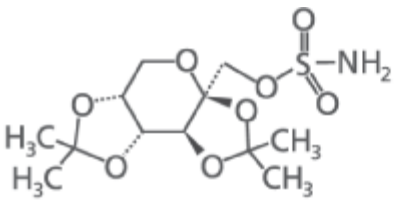
Chapter 40. Topiramate

HISTORY AND DISCOVERY

Topiramate is a derivative of the naturally occurring monosaccharide D-fructose. It was originally synthesized to be a structural analog of fructose-1,6-diphosphatase as part of a project to develop agents that inhibit gluconeogenesis by inhibiting the enzyme fructose-1,6-biphosphatase (Shank et al. 2000). To date, however, it has not been shown by clinical evidence to have direct hypoglycemic activity. Topiramate contains a sulfamate moiety. The structural resemblance of this moiety to the sulfonamide moiety in the established antiepileptic drug acetazolamide prompted researchers to evaluate topiramate for possible anticonvulsant effects. Topiramate subsequently was shown to have potent anticonvulsant properties in a broad range of preclinical epilepsy models (Shank et al. 2000).



The drug's efficacy in patients with epilepsy was established in the early 1990s. These studies also showed that topiramate had a favorable pharmacokinetic profile, had a high therapeutic index, was not associated with hematological or hepatic abnormalities, did not require routine serum concentration monitoring, and was associated with anorexia and weight loss (rather than appetite stimulation and weight gain like some other antiepileptic drugs) (Langtry et al. 1997). Topiramate was approved by the U.S. Food and Drug Administration (FDA) for the treatment of epilepsy in 1996. It was approved for migraine prevention in adults in 2004.

Reports appearing in the late 1990s of the drug having potential beneficial effects in bipolar disorder led Johnson and Johnson Pharmaceutical Research and Development (PRD), the discoverer and manufacturer of topiramate, to conduct a large clinical study program of topiramate in the treatment of acute bipolar mania (McElroy and Keck 2004). Controlled trials of the drug in bipolar adults with manic symptoms failed to demonstrate significant separation between the topiramate and placebo groups (Chengappa et al. 2006; Kushner et al. 2006). However, topiramate has been shown to be efficacious in placebo-controlled trials in several neuropsychiatric conditions often comorbid with bipolar disorder, including, in addition to migraine, binge-eating disorder (BED), bulimia nervosa, alcohol dependence, borderline personality disorder (BPD), psychotropic-associated weight gain, and obesity.

STRUCTURE–ACTIVITY RELATIONS

Topiramate is a sulfamate-substituted monosaccharide derived from D-fructose (Figure 40–1). As such, it is structurally distinct from other antiepileptic medications. Its sulfamate moiety is essential for its pharmacological activity (Shank et al. 2000). It has been postulated that topiramate's multiple pharmacological properties (which are discussed in the following section) are regulated by protein phosphorylation. Specifically, it has been hypothesized that topiramate interacts with voltage-activated sodium channels, γ-aminobutyric acid (GABA) type A ($GABA_A$) receptors, α-amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid (AMPA)/kainate glutamate receptors, and high-voltage-activated calcium channels via formation of hydrogen bonds between proton-accepting oxygens in its sulfamate moiety and proton donor groups in tetrapeptide sequences in the latter (Shank et al. 2000).

PHARMACOLOGICAL PROFILE

Topiramate has multiple pharmacological properties that may contribute to its anticonvulsant effects, as well as its therapeutic effects in other neuropsychiatric disorders (Langtry et al. 1997; Rho and Sankar 1999; Rosenfeld 1997; Shank et al. 2000; White 2002, 2005; White et al. 2007). First, topiramate inhibits voltage-gated sodium channels in a voltage-sensitive, use-dependent manner and thus suppresses action potentials associated with sustained repetitive cell firing (Kawasaki et al. 1998; Shank et al. 2000).

Second, topiramate increases brain GABA levels, possibly by activating a site on the $GABA_A$ receptor, thereby enhancing the inhibitory chloride ion influx mediated by the $GABA_A$ receptor and potentiating GABA-evoked currents (Kuzniecky et al. 1998; Petroff et al. 2001; Simeone et al. 2006). Because this action is not blocked by the benzodiazepine antagonist flumazenil, it is thought that topiramate exerts this effect via an interaction with the $GABA_A$ receptor that is not modulated by benzodiazepines (White et al. 2000). This action may also be sensitive to GABA concentrations and $GABA_A$ receptor subunit composition (Simeone et al. 2006).

Third, topiramate antagonizes glutamate receptors of the AMPA/kainate subtype and may selectively inhibit glutamate receptor 5 ($GluR_5$) kainate receptors (Kaminski et al. 2004). It has essentially no effect on glutamate *N*-methyl-D-aspartate (NMDA) receptors. AMPA/kainate receptors mediate fast excitatory postsynaptic potentials responsible for excitatory neurotransmission; blockade of kainate-evoked currents decreases neuronal excitability.

Fourth, topiramate negatively modulates high-voltage-activated calcium channels (Zhang et al. 2000). Of note, Shank et al. (2000) proposed that topiramate's combined effects on voltage-activated sodium channels, $GABA_A$ receptors, AMPA/kainate receptors, and high-voltage-activated calcium channels are unique as compared with those of other antiepileptic drugs. Indeed, Schiffer et al. (2001) found that pretreatment with topiramate inhibited nicotine-induced increases in mesolimbic extracellular dopamine and norepinephrine but not serotonin. They hypothesized that this property was a result of the drug's ability to affect both GABAergic and glutamatergic function.

Fifth, topiramate has weak inhibitory actions against some carbonic anhydrase isoenzymes, including subtypes II and VI. Carbonic anhydrase is essential for the generation of $GABA_A$-mediated depolarizing responses. By inhibiting carbonic anhydrase, topiramate has been shown to reversibly reduce the $GABA_A$-mediated depolarizing responses evoked by either synaptic stimulation or pressure application of GABA (but not to modify $GABA_A$-mediated hyperpolarizing postsynaptic potentials) (Herrero et al. 2002). As a result of the effects of carbonic anhydrase inhibition on intracellular pH, topiramate also may activate a potassium conductance (Herrero et al. 2002).

Finally, topiramate has been shown to have a number of other properties. These include an interaction with glycine receptor channels (Mohammadi et al. 2005), effects on mitochondrial permeability (Kudin et al. 2004), and antikindling properties in some animal models (Wauguier and Zhou 1996).

PHARMACOKINETICS AND DISPOSITION

Topiramate has a favorable pharmacokinetic profile (Bialer et al. 2004; Doose and Streeter 2002; Langtry et al. 1997; Rosenfeld 1997; Shank et al. 2000). It is rapidly and almost completely absorbed after oral administration, with bioavailability estimated to be about 80%. Peak plasma concentrations are reached within 2–4 hours. Plasma concentration increases in proportion to dose over the pharmacologically relevant dose range.

The volume of distribution of topiramate is inversely proportional to the dose, with the drug distributed primarily to body water. It is minimally protein-bound (9%–17%).

Topiramate is minimally metabolized by the liver in the absence of hepatic enzyme–inducing drugs. It inhibits cytochrome P450 (CYP) enzyme 2C19 but not other hepatic CYP enzymes. Topiramate is excreted mostly unchanged (approximately 70%) in the urine. The nonrenal (hepatic) clearance of topiramate increases two- to threefold when the drug is administered with hepatic enzyme–inducing drugs such as carbamazepine and phenytoin. Six minor metabolites have been identified (Shank et al. 2000).

Topiramate's elimination half-life is 19–25 hours, with linear pharmacokinetics in the dose range of 100–1,200 mg. The pharmacokinetics of topiramate in children are similar to those in adults, except that clearance is 50% higher, resulting in 33% lower plasma concentrations. Moderate or severe renal failure is associated with reduced renal clearance and increased elimination half-life of topiramate. Moderate or severe liver impairment is associated with clinically insignificant increased plasma concentrations of the drug.

MECHANISM OF ACTION

Although the mechanism of topiramate's anticonvulsant action is unknown, it has been hypothesized to be due to some combination of the drug's multiple pharmacological properties (Rho and Sankar 1999; Shank et al. 2000; White 2002, 2005; White et al. 2007).

As discussed, these include state-dependent blockade of voltage-activated sodium channels, enhancement of GABA activity at the $GABA_A$ receptor via interaction with a nonbenzodiazepine receptor site, antagonism of the AMPA/kainate glutamate receptor, antagonism of high-voltage-activated calcium channels, and inhibition of carbonic anhydrase. For example, the drug's anticonvulsant profile, as well as its benefits in substance use and eating disorders, has been hypothesized to be due to its dual actions on the GABAergic and glutamatergic systems (Johnson et al. 2003, 2005; McElroy et al. 2003, 2007b; Rho and Sankar 1999; Schiffer et al. 2001). By contrast, carbonic anhydrase inhibition is thought by some not to play a large role in topiramate's anticonvulsant properties despite acetazolamide's clinical efficacy as an antiepileptic because of topiramate's much weaker potency as an inhibitor (Rho and Sankar 1999). Others, however, have suggested that topiramate's inhibition of carbonic anhydrase contributes to its anticonvulsant properties via reduction of $GABA_A$-mediated depolarizing responses and/or activation of a potassium conductance (Herrero et al. 2002).

INDICATIONS AND EFFICACY

FDA-Approved Indications

Topiramate is currently indicated by the FDA as initial monotherapy in patients 10 years of age and older with partial-onset or primary generalized tonic-clonic seizures; as adjunctive therapy for adults and pediatric patients ages 2–16 years with partial-onset seizures or primary generalized tonic-clonic seizures; and in patients 2 years of age and older with seizures associated with Lennox-Gastaut syndrome (van Passel et al. 2006). It is also indicated for the prophylaxis of migraine headache in adults (Brandes 2005; Bussone et al. 2006).

Other Indications

Topiramate is not currently approved by the FDA for use in the treatment of any psychiatric disorder. Because the drug was widely used off-label in the treatment of bipolar disorder after it came to market (see subsection "Bipolar Disorder" below), Johnson and Johnson PRD, the discoverer of topiramate, conducted a large study program of topiramate in adults with acute bipolar mania. These placebo-controlled studies failed to demonstrate a significant benefit of topiramate over placebo on the Young Mania Rating Scale (YMRS) (Chengappa et al. 2001a; Kushner et al. 2006; McElroy and Keck 2004). In contrast, a placebo-controlled trial in pediatric mania, which was prematurely discontinued in the aftermath of the failed adult trials, did show significant efficacy results favoring topiramate based on a retrospective analysis of 56 patients (DelBello et al. 2005).

Topiramate has been studied in the treatment of a variety of other neuropsychiatric disorders, many of which co-occur with bipolar disorder. Data from placebo-controlled clinical trials suggest that topiramate is efficacious in BED with obesity (McElroy et al. 2003, 2007b), bulimia nervosa (Hedges et al. 2003; Hoopes et al. 2003; C. Nickel et al. 2005b), alcohol dependence (Johnson et al. 2003, 2007), psychotropic-induced weight gain (Ko et al. 2005; M. K. Nickel et al. 2005b), obesity (McElroy et al. 2008), and neuropathic pain (Raskin et al. 2004). These and other studies will be reviewed below.

Bipolar Disorder

Five randomized, placebo-controlled studies have shown that topiramate monotherapy is not efficacious in the short-term treatment of acute manic or mixed episodes in adults with bipolar I disorder (Kushner et al. 2006; McElroy and Keck 2004). All five studies used week 3 as the primary endpoint; in addition, three studies had a week 12 secondary endpoint, two studies had lithium comparator groups, and all trials measured weight as a secondary outcome. Analyses of the 3-week data from all five trials were consistent. In each trial, the primary efficacy outcome—the change from baseline to week 3 in the YMRS score—failed to show a statistically significant separation between topiramate and placebo. There was also no drug–placebo separation in the three trials with week 12 data. By contrast, in the two trials in which lithium was used, lithium did show statistical superiority to placebo. Topiramate, however, showed significant separation from placebo in weight loss, whereas lithium was associated with statistically significant weight gain.

Similarly, in the only placebo-controlled study of adjunctive topiramate in bipolar disorder, 287 outpatients experiencing a manic or mixed episode (by DSM-IV [American Psychiatric Association 1994] criteria) and a YMRS score ≥18 while taking therapeutic levels of valproate or lithium showed similar reductions (40%) in baseline YMRS scores for both topiramate and placebo after 12 weeks (Chengappa et al. 2006). Topiramate, however, was again associated with significant weight loss as compared to placebo.

Despite the negative results of the adult acute mania trials, numerous clinical reports suggest that topiramate may have a role in the management of bipolar disorder. In the only placebo-controlled study of topiramate in pediatric bipolar I disorder, 56 children and adolescents (6–17 years) with manic or mixed episodes were randomly assigned to topiramate (n = 29) or placebo (n = 27) for 4 weeks (DelBello et al. 2005). Initially designed to enroll approximately 230 subjects, the study was prematurely discontinued when the adult mania trials were negative. Decrease in mean YMRS score from baseline to final visit using last observation carried forward (LOCF) was not statistically different between treatment groups (–9.7 ± 9.65 for topiramate vs. –4.7 ± 9.79 for placebo, P = 0.152). However, a post hoc repeated-measures linear regression model of the primary efficacy analysis showed a statistically significant difference in the slopes of the linear mean profiles (P = 0.003).

No placebo-controlled study of topiramate has yet been done in acute bipolar depression. Results from an 8 week single-blind comparison trial in which 36 outpatient adults with bipolar depression were randomly assigned to receive either topiramate (mean dosage = 176 mg/day; range = 50–300 mg/day) or bupropion SR (sustained release) (mean dosage = 250 mg/day; range = 100–400

mg/day) suggested that the drug might have antidepressant properties in some bipolar patients (McIntyre et al. 2002). The percentage of patients meeting a priori response criteria (50% or greater decrease from baseline in mean total score on the 17-item Hamilton Rating Scale for Depression [Ham-D]) was significant for both topiramate (56%) and bupropion SR (59%). There were no cases of manic switching with either drug. Moreover, numerous open-label reports have described patients with milder forms of bipolarity (i.e., "soft" bipolar spectrum disorders), including those with mixed states or rapid cycling, that respond to topiramate (McElroy and Keck 2004; McElroy et al. 2000; McIntyre et al. 2005).

Finally, a number of open-label reports have described the successful topiramate treatment of bipolar disorder with various comorbid psychiatric or general medical disorders ("complicated" bipolar disorder). Comorbid psychiatric conditions in which improvement was seen included alcohol abuse; anxiety disorders such as obsessive-compulsive disorder (OCD) and posttraumatic stress disorder (PTSD); eating disorders such as bulimia nervosa, BED, and anorexia nervosa; impulse-control disorders; and catatonia (Barzman and DelBello 2006; Guille and Sachs 2002; Huguelet and Morand-Collomb 2005; McDaniel et al. 2006; McElroy et al. 2008; Shapira et al. 2000). Comorbid general medical conditions in which improvement was seen included obesity, psychotropic-induced weight gain, type 2 diabetes mellitus, tremor, and Tourette's disorder (Chengappa et al. 2001b; Guille and Sachs 2002; McIntyre et al. 2005; Vieta et al. 2002).

These observations call for controlled studies of topiramate in pediatric bipolar disorder, acute bipolar depression, bipolar II disorder and other "softer" forms of bipolar disorder, and complicated bipolar disorder. No controlled maintenance or prophylactic treatment studies of topiramate in bipolar disorder have yet been completed.

Depressive Disorders

In the only controlled study of topiramate in a depressive disorder, 64 females with DSM-IV recurrent major depressive disorder were randomly assigned to topiramate (n = 32) or placebo (n = 32) for 10 weeks (C. Nickel et al. 2005a). Topiramate was superior to placebo in reducing depressive and anger symptoms (as assessed by the Ham-D [P = 0.02] and the State-Trait Anger Expression Inventory [STAXI; P < 0.001 on all scales]), respectively, and on most scales of the SF-36 Health Survey (all Ps between 0.15 and 0.001). The reduction in expression of anger correlated significantly with changes on the Ham-D. Five subjects (2 topiramate, 3 placebo) were lost to follow-up. Weight loss was greater in the topiramate group by 4.2 kg (P < 0.001). All subjects tolerated topiramate well, and there were no suicidal events.

Psychotic Disorders

Two randomized, placebo-controlled studies of topiramate targeting psychopathology in psychotic disorders have been conducted. In the first, 26 patients with treatment-resistant schizophrenia had topiramate (gradually increased to 300 mg/day) or placebo added to their ongoing treatment (clozapine, olanzapine, risperidone, or quetiapine) over two 12-week crossover treatment periods (Tiihonen et al. 2005). In the intent-to-treat analysis, topiramate was superior to placebo in reducing general psychopathological symptoms as assessed by the Positive and Negative Syndrome Scale (PANSS), but no significant improvement was observed in positive or negative symptoms.

In the second study, 48 patients with schizoaffective disorder, bipolar type, were randomly assigned in a 2:1 ratio (favoring topiramate) to 8 weeks of double-blind treatment with topiramate (100–400 mg/day) or placebo (Chengappa et al. 2007). Patients who had achieved ≥20% decrease from baseline in their PANSS total scores were given the opportunity to continue for an additional 8 weeks of double-blind treatment. Study medication dosage was continued unchanged from the earlier 8-week study period. Adjunctive topiramate (nearly 275 mg/day) did not show increased efficacy relative to placebo on the PANSS (the primary outcome measure) or on any of the secondary outcome

measures. Topiramate-treated patients lost significantly more body weight than did placebo-treated patients, but they also experienced higher rates of paresthesias, sedation, word-finding difficulty, sleepiness, and forgetfulness.

Case reports regarding topiramate's effectiveness as an adjunct treatment in schizophrenia have been inconsistent, with improvement, no change, and deterioration in clinical state all being described (Citrome 2008). However, there are several case reports of the successful use of topiramate to treat catatonia in patients with chronic psychotic disorders (McDaniel et al. 2006).

Eating Disorders

Five randomized, placebo-controlled studies have shown that topiramate reduces binge eating and excessive body weight in 640 subjects with bulimia nervosa (*n* = 2 studies, 99 subjects) or BED (*n* = 3 studies, 541 subjects). In the first study in bulimia nervosa, a 10-week trial in 69 subjects, topiramate (median dosage = 100 mg/day; range = 25–400 mg/day) was superior to placebo in reducing the frequency of binge and purge days (days during which at least one binge-eating or purging episode occurred; *P* = 0.004); decreasing scores on the bulimia/uncontrollable overeating (*P* = 0.005), body dissatisfaction (*P* = 0.007), and drive for thinness (*P* = 0.002) subscales of the Eating Disorder Inventory; decreasing scores on the bulimia/food preoccupation (*P* = 0.019) and dieting (*P* = 0.031) subscales of the Eating Attitudes Test; and reducing body weight (mean decrease of 1.8 kg for topiramate vs. 0.2 kg mean increase for placebo; *P* = 0.004) (Hedges et al. 2003; Hoopes et al. 2003). Binge-eating/purging remission rates were 32% for topiramate and 6% for placebo (*P* = NS). Dropout rates were 34% for topiramate and 47% for placebo. In the second study, 60 subjects with DSM-IV bulimia nervosa for at least 12 months received 10 weeks of topiramate (titrated to 250 mg/day in the sixth week) (*n* = 30) or placebo (*n* = 30) (C. Nickel et al. 2005b). Topiramate was associated with significant decreases in binge/purge frequency (defined as a >50% reduction; 37% for topiramate and 3% for placebo), body weight (difference in weight loss between the 2 groups = 3.8 kg), and all of the SF-36 Health Survey scales (all *P*s <0.001). Five (17%) subjects on topiramate and 6 (20%) subjects on placebo were dropouts.

In the first controlled study in BED, 61 subjects with DSM-IV BED and obesity (defined as a body mass index [BMI] ≥30) received topiramate (*n* = 30) or placebo (*n* = 31) for 14 weeks (McElroy et al. 2003). Topiramate was significantly superior to placebo in reducing binge frequency, as well as global severity of illness, obsessive-compulsive features of binge-eating symptoms, body weight, and BMI. Topiramate-treated subjects experienced a 94% reduction in binge frequency and a mean weight loss of 5.9 kg, whereas placebo-treated subjects experienced a 46% reduction in binge frequency and a mean weight loss of 1.2 kg. The dropout rate, however, was high—14 (47%) subjects receiving topiramate and 12 (39%) subjects receiving placebo failed to complete the trial.

The second controlled study of topiramate in BED was a multicenter trial in which subjects with DSM-IV BED and ±3 binge-eating days per week, a BMI ranging from 30 kg/m^2 to 50 kg/m^2, and no current psychiatric disorders or substance abuse were randomly assigned in a 1:1 ratio to topiramate or placebo for 16 weeks (McElroy et al. 2007b). Of 407 subjects enrolled, 13 failed to meet inclusion criteria; 95 topiramate and 199 placebo subjects were therefore evaluated for efficacy. Topiramate significantly reduced binge-eating days per week (–3.5 ± 1.9 vs. –2.5 ± 2.1), binge episodes per week (–5 ± 4.3 vs. –3.4 ± 3.8), weight (–4.5 ± 5.1 kg vs. 0.2 ± 3.2 kg), and BMI (–1.6 ± 1.8 kg/m^2 vs. 0.1 ± 1.2 kg/m^2) compared with placebo (all *P*s <0.001). The drug also significantly decreased measures of obsessive-compulsive symptoms, impulsivity, hunger, and disability. Fifty-eight percent of topiramate-treated subjects achieved remission compared with 29% of placebo-treated subjects (*P* <0.001). Discontinuation rates were 30% in each group; adverse events were the most common reason for topiramate discontinuation (16%; placebo, 8%).

The third controlled study of topiramate in BED was another multicenter trial in which 73 patients with

BED and obesity were randomly assigned to 19 sessions of cognitive-behavior therapy in conjunction with topiramate (*n* = 37) or placebo (*n* = 36) for 21 weeks (Claudino et al. 2007). Compared with patients given placebo, patients given topiramate showed a significantly greater rate of reduction in weight, the primary outcome measure, over the course of treatment (*P* <0.001). Topiramate recipients also showed a significant weight loss (−6.8 kg) relative to placebo recipients (−0.9 kg). Rates of reduction of binge frequencies and scores on the Binge Eating Scale and BDI did not differ between the groups, but a greater percentage of topiramate-treated patients (31 of 37) than of placebo-treated patients (22 of 36) attained remission of binge eating (*P* = 0.03). There was no difference between groups in completion rates, although one topiramate recipient withdrew because of an adverse effect.

In open studies, topiramate has also been reported to have long-term therapeutic effects in BED with obesity; to reduce symptoms of BED, bulimia nervosa, and anorexia nervosa with comorbid mood disorders; and to reduce nocturnal eating and overweight in patients with night-eating syndrome and sleep-related eating disorders (Guille and Sachs 2002; McElroy et al. 2008; Winkelman 2006). However, there is a report of topiramate possibly "triggering" a recurrent episode of anorexia nervosa in a woman with epilepsy and several reports of eating disorder patients misusing the drug to lose weight (McElroy et al. 2008).

Substance Use Disorders

Four randomized, placebo-controlled studies suggest that topiramate may have therapeutic effects in alcohol, cocaine, and nicotine dependence. Two studies examined topiramate in alcohol dependence. In the first, 150 subjects with alcohol dependence were randomly assigned to topiramate (*n* = 75; up to 300 mg/day) or placebo (*n* = 75) for 12 weeks (Johnson et al. 2003). All subjects received compliance enhancement therapy. At study end, subjects receiving topiramate, compared with those on placebo, had 2.88 (95% CI = −4.50 to −1.27) fewer drinks per day (*P* = 0.0006), 3.10 (95% CI = −4.88 to −1.31) fewer drinks per drinking day (*P* = 0.0009), 27.6% fewer heavy drinking days (*P* = 0.0003), 26.2% more days abstinent (*P* = 0.0003), and a log plasma gamma-glutamyl transferase (GGT) ratio of 0.07 (−0.11 to −0.02) less (*P* = 0.0046). Changes in craving were also significantly greater with topiramate than with placebo. In the second study, 371 subjects were randomly assigned to topiramate (up to 300 mg) or placebo, along with a weekly compliance enhancement intervention, at 16 sites for 14 weeks (Johnson et al. 2007). Topiramate was significantly superior to placebo in reducing the percentage of heavy drinking days and other drinking outcomes, such as drinks per drinking day, percentage of days abstinent, and log plasma GGT ratio (all *P*s ≤0.002).

In the study in cocaine dependence, 40 subjects were randomly assigned to topiramate (titrated gradually over 8 weeks to 200 mg/day) or placebo for 13 weeks (Kampman et al. 2004). Topiramate-treated subjects were more likely to be abstinent from cocaine after week 8 compared with placebo-treated subjects (*P* = 0.01). They were also more likely to achieve 3 weeks of continuous abstinence from cocaine (*P* = 0.05).

In the first of two controlled studies in smoking cessation, topiramate (*n* = 45) was superior to placebo (*n* = 49) in 94 male and female subjects with comorbid alcohol dependence (Johnson et al. 2005). This study was a subgroup analysis of the first controlled study of topiramate in alcohol dependence (Johnson et al. 2003). In the second study, the drug (*n* = 43) was superior to placebo (*n* = 44) for smoking cessation in male (*n* = 38), but not female (*n* = 49), subjects who had no associated psychopathology (Anthenelli et al. 2008).

There have also been case reports of the successful use of topiramate in opiate and benzodiazepine withdrawal, but these uses will need to be evaluated in placebo-controlled trials (Michopoulos et al. 2006; Zullino et al. 2004).

Anxiety Disorders

Topiramate has been evaluated in one controlled study of PTSD. Thirty-eight patients with non-combat-related PTSD were randomly assigned to flexible doses of topiramate (median dosage = 150 mg/day, range = 25–400 mg/day) or placebo for 12 weeks (Tucker et al. 2007). No significant difference was found on the primary efficacy measure, the total Clinician-Administered PTSD Scale (CAPS) score. However, significant or near significant effects were found in favor of topiramate on the eight-item Treatment Outcome PTSD scale (TOP-8) (decrease in overall severity 68% vs. 41.6%; *P* = 0.025) and endpoint Clinical Global Impression Scale—Improvement (CGI-I) scores (1.9 ± 1.2 vs. 2.6 ± 1.1; *P* = 0.055).

Open-label studies suggest that topiramate may have therapeutic effects in generalized social phobia and OCD (Mula et al. 2007). In contrast, there are case reports of patients experiencing panic attacks apparently induced by topiramate (Damsa et al. 2006).

Borderline Personality Disorder

Three placebo-controlled studies, all conducted by the same group, have evaluated topiramate in DSM-IV-defined BPD. In the first, 29 female subjects were randomly assigned in a 2:1 ratio to topiramate (*n* = 21, analysis based on 19) or placebo (*n* = 10) for 8 weeks (M. K. Nickel et al. 2004). Topiramate dosage was increased to 250 mg/day over 6 weeks. At study end, significant improvement on four subscales of the STAXI (state–anger, trait–anger, anger–out, and anger–control) was observed for topiramate compared with placebo. In the second study, 42 male subjects with BPD received topiramate (*n* = 22) or placebo (*n* = 20) for 8 weeks (M. K. Nickel et al. 2005a). Similar to the study in females, significant improvement on the same four subscales on the STAXI was found for topiramate compared with placebo. In the third study, 56 women with BPD received topiramate (*n* = 28) or placebo (*n* = 28) for 10 weeks (Loew et al. 2006). Topiramate was titrated to 200 mg/day over 6 weeks and then held constant. Topiramate was superior to placebo on the somatization, interpersonal sensitivity, anxiety, hostility, phobic anxiety, and Global Severity Index subscales of the Symptom Checklist (SCL-90-R) (all *P*s <0.001); all eight scales of the SF-36 Health Survey (all *P*s <0.01); and four of eight scales of the Inventory of Interpersonal Problems (all *P*s <0.001). Four patients (1 on topiramate, 3 on placebo) dropped out. In all three studies, topiramate was associated with significantly greater weight loss then placebo. It was also well tolerated, and there were no psychotic or suicidal adverse events.

Psychotropic-Associated Weight Gain

Two placebo-controlled studies suggest that topiramate reduces antipsychotic-induced weight gain in schizophrenia. In one study, 66 inpatients with schizophrenia receiving antipsychotic medication and "carrying excess weight" were randomly assigned to topiramate 100 mg/day, topiramate 200 mg/day, or placebo for 12 weeks (Ko et al. 2005). Body weight, BMI, and waist and hip circumference decreased significantly in the topiramate 200 mg/day group compared with the topiramate 100 mg/day and placebo groups. Scores on the Clinical Global Impression Scale—Severity of Illness (CGI-S) and the Brief Psychiatric Rating Scale (BPRS) were also significantly decreased, but the decreases were not thought to be clinically meaningful. In the other study, 43 women with mood or psychotic disorders who had gained weight while receiving olanzapine were given topiramate (*n* = 25) or placebo (*n* = 18) for 10 weeks (Nickel et al. 2005b). Weight loss was significantly greater (by 5.6 kg) in the topiramate group. Topiramate-treated subjects also experienced significantly greater improvement in measures of health-related quality of life and psychological impairment.

One placebo-controlled study and two randomized comparison trials suggest that topiramate may be superior to placebo and at least as effective as bupropion and sibutramine in psychotropic-associated weight gain in bipolar patients. In the controlled study in bipolar I manic or mixed patients receiving lithium or valproate, adjunctive topiramate was ineffective for manic symptoms but was associated with significantly greater reductions in body weight compared with placebo (–2.5 vs. 0.2 kg,

respectively; *P* <0.001) and BMI (–0.84 vs. 0.07 kg/m^2, respectively; *P* <0.001) (Chengappa et al. 2006). In a single-blind comparator trial in 36 outpatients with bipolar depression, adjunctive bupropion and topiramate showed similar rates of antidepressant response (59% vs. 56%), but topiramate was associated with a greater mean weight loss (5.8 kg vs. 1.2 kg) (McIntyre et al. 2002). In a 24-week open-label, flexible-dose comparison trial, 46 euthymic outpatients with a bipolar disorder (types I, II, or not otherwise specified [NOS]) who had a BMI ≥30 kg/m^2, or a BMI ≥27 with obesity-related medical comorbidities, and psychotropic-associated weight gain (defined as a weight gain of 10 lbs [4.5 kg] since initiation of their current psychotropic regimen) were randomly assigned to receive topiramate (*n* = 28; 25–600 mg/day) or sibutramine (*n* = 18; 5–15 mg/day) for 24 weeks (McElroy et al. 2007a). Patients receiving either drug lost comparable amounts of weight (2.8 ± 3.5 kg for topiramate and 4.1 ± 5.7 kg for sibutramine) and displayed similar rates of weight loss (0.82 kg/week and 0.85 kg/week, respectively). However, only 4 (22%) patients receiving sibutramine and 6 (21%) patients receiving topiramate completed the trial. In addition, the attrition patterns for the two drugs were different, with patients discontinuing topiramate doing so early in treatment and patients discontinuing sibutramine doing so throughout treatment.

Several open-label, prospective trials suggest that initiating treatment with the combination of topiramate with either risperidone or olanzapine may successfully stabilize mood in patients with bipolar disorder while preventing weight gain (Bahk et al. 2005; Vieta et al. 2003, 2004). Finally, topiramate has also been used to treat weight gain in patients with major depression receiving antidepressants, patients with anxiety disorders receiving selective serotonin reuptake inhibitors, and patients with autism receiving antipsychotics (McElroy et al. 2008).

Obesity

Nine randomized, placebo-controlled trials have evaluated topiramate (Astrup et al. 2004; Bray et al. 2003; Eliasson et al. 2007; Stenlöf et al. 2007; Tonstad et al. 2005; Toplak et al. 2007; Tremblay et al. 2007; Wilding et al. 2004) or a controlled-release (CR) formulation of topiramate (Rosenstock et al. 2007) for weight loss in subjects with obesity. In one study, subjects were required to have comorbid essential hypertension (Tonstad et al. 2005); in four studies, subjects were required to have concurrent type 2 diabetes (Eliasson et al. 2007; Rosenstock et al. 2007; Stenlöf et al. 2007; Toplak et al. 2007). In all nine studies, topiramate was superior to placebo for weight loss at all doses (range 64–400 mg/day) and at all endpoints (range 28 weeks to 1 year) evaluated. The four long-term studies (duration 40 weeks to 1 year) showed that topiramate was associated with weight loss that increased up to 1 year without plateauing (Astrup et al. 2004; Eliasson et al. 2007; Stenlöf et al. 2007; Wilding et al. 2004). In the study of topiramate in obese subjects with comorbid hypertension, there were significant decreases in diastolic, but not systolic, blood pressure in the two groups receiving topiramate compared with the placebo group. In the four studies of topiramate in obese subjects with comorbid type 2 diabetes, topiramate-treated patients showed significant decreases in glycosylated hemoglobin (Hb_{A1c}) compared with placebo-treated patients.

Neuropathic Pain and Other Neurological Conditions

Five randomized, placebo-controlled studies of topiramate in painful diabetic neuropathy have produced mixed results. Three similarly designed trials in 1,259 subjects with moderate or extreme pain evaluating topiramate at 100 mg, 200 mg, or 400 mg/day did not find statistical separation on the 100-mm Visual Analog Scale (VAS) after 18–22 weeks of treatment (Thienel et al. 2004). Across all studies, 24% of topiramate-treated subjects and 8% of placebo-treated subjects discontinued treatment due to adverse events; groups did not differ in the occurrence of serious adverse events.

The other two controlled studies showed separation between topiramate and placebo in 345 subjects (Raskin et al. 2004). In the larger trial (*N* = 323), subjects with a pain visual analog (PVA) scale score of at least 40 (on a scale of 0 [no pain] to 100 mm [worst possible pain]) were given topiramate (up

to 400 mg/day; *n* = 214) or placebo (*n* = 109) for 12 weeks (Raskin et al. 2004). Topiramate was associated with significantly greater reductions in the PVA scale score (*P* = 0.038), the worst pain intensity score (*P* = 0.003), and sleep disruption (*P* = 0.020). Topiramate also reduced body weight (–2.6 vs. +0.2 kg for placebo; *P* < 0.001) without disrupting glycemic control.

Regarding other neurological conditions, topiramate has been shown superior to placebo in controlled trials in preventing pediatric migraine (Winner et al. 2005) and treating essential tremor (Ondo et al. 2006). Open data suggest that topiramate may have beneficial effects in cluster headache (Pascual et al. 2007).

SIDE EFFECTS AND TOXICOLOGY

The side-effect profile of topiramate may vary with the patient's illness, mood state, and concomitant medications. The most common side effects of topiramate in the initial dose-ranging studies in patients with epilepsy when used in combination with other antiepileptic drugs at dosages of 200–1,000 mg/day were related to the central nervous system and included dizziness, somnolence, psychomotor slowing, nervousness, paresthesias, ataxia, difficulty with memory, difficulty with concentration or attention, confusion, and speech disorders or related speech problems (Langtry et al. 1997; Shorvon 1996). Other side effects were nystagmus, depression, nausea, diplopia, abnormal vision, anorexia, language problems, and tremor. When used as monotherapy in patients with epilepsy, the most common side effects were dizziness, anxiety, paresthesias, insomnia, somnolence, myalgia, anorexia, nausea, dyspepsia, and diarrhea. The most common side effects of topiramate in the large registration trials for migraine (which used total daily doses of 50, 100, and 200 mg) were paresthesias, fatigue, memory difficulties, concentration/attention problems, and mood problems (Bussone et al. 2006). In the monotherapy trials in adult mania, paresthesias, decreased appetite, dry mouth, and weight loss were more common with topiramate than placebo (Kushner et al. 2006). In the adolescent mania trial, the most common adverse events occurring with topiramate were decreased appetite, nausea, diarrhea, paresthesias, somnolence, insomnia, and rash (DelBello et al. 2005). In the obesity trials, events related to the central or peripheral nervous systems or to psychiatric disorders were most commonly reported (Rosenstock et al. 2007). These included paresthesias; fatigue; difficulty with attention, concentration and/or memory; taste perversion; and anorexia. Overall, paresthesias and cognitive complaints are the most troublesome adverse events (van Passel et al. 2006).

The central nervous system and gastrointestinal effects of topiramate are usually mild to moderate in severity and often decrease or resolve with time or dosage reduction (Meador et al. 2003; Shorvon 1996). Also, they may be minimized by slow titration of topiramate dosage (Biton et al. 2001). However, topiramate may be associated with more cognitive impairment than some of the other new antiepileptic drugs (Martin et al. 1999; Meador et al. 2003).

Infrequent but serious side effects of topiramate include nephrolithiasis, an ocular syndrome of acute myopia with secondary angle-closure glaucoma, oligohydrosis and hyperthermia, and metabolic acidosis (van Passel et al. 2006). The incidence of nephrolithiasis has been estimated to be 1.5% (Shorvon 1996). In the epilepsy trials, more than 75% of the patients who developed renal stones elected to continue treatment with topiramate (Reife et al. 2000). Nephrolithiasis is thought to be related to topiramate exerting carbonic anhydrase inhibition in the kidney (Welch et al. 2006).

The secondary angle-closure glaucoma associated with topiramate is characterized by acute onset of bilateral blurred vision and ocular pain (Fraunfelder and Fraunfelder 2004; Fraunfelder et al. 2004). Ophthalmological findings include bilateral myopia, conjunctival hyperemia, anterior chamber shallowing, and increased intraocular pressure. Most cases have occurred within 1 month of topiramate initiation and fully resolve with drug discontinuation. Peripheral iridectomy or laser iridotomy are not effective. The syndrome has been attributed to sulfamate-induced ciliary body

edema.

There were no clinically relevant changes in hepatic, renal, or hematological parameters in the registration trials of topiramate, and laboratory monitoring was initially thought not to be required (Reife et al. 2000; Sachdeo and Karia 2002). In addition, no treatment-related changes in physical or neurological examinations (except body weight loss; see next paragraph), in the electrocardiogram, or in ophthalmological or audiometric test results were noted. However, as a carbonic anhydrase inhibitor, topiramate reduces serum bicarbonate levels, and it is believed that this is the mechanism underlying reports of reversible metabolic acidosis in some patients (Sachdeo and Karia 2002; van Passel et al. 2006; Welch et al. 2006). It is now recommended that baseline and periodic serum bicarbonate levels be measured in patients receiving topiramate. A case of liver failure in a young woman with epilepsy after addition of topiramate to carbamazepine (Bjoro et al. 1998) and a case of significant liver enzyme elevation in another young woman with bipolar disorder and obesity after addition of topiramate to divalproex sodium, benztropine, risperidone, clonazepam, and an oral contraceptive (Doan and Clendenning 2000) have been reported. To date, no cases of liver failure have been reported with topiramate monotherapy.

A growing concern is the psychiatric adverse-event profile of antiepileptic drugs in patients with epilepsy, including whether such drugs cause suicidality and psychosis. Although some data suggest that a subgroup of epilepsy patients may be susceptible to such psychiatric adverse events, other data indicate that topiramate may be associated with depression in epilepsy patients, especially during rapid titration (Mula and Sander 2007). There are also isolated reports of the drug inducing mood and anxiety symptoms in psychiatric patients (Damsa et al. 2006; Klufas and Thompson 2001). Moreover, one obesity study reported eight (6.2%) suicidal-related events occurring in topiramate-treated subjects versus none in placebo-treated subjects (Rosenstock et al. 2007).

Body weight loss in patients enrolled in clinical trials for epilepsy was reported as an adverse event in 7% of the patients receiving topiramate 200–400 mg/day and 13% of the patients receiving topiramate 600–1,000 mg/day, compared with 3% of the placebo-treated patients (Reife et al. 2000). Weight loss was associated with anorexia and was more common in heavier patients. Degree of weight loss was dose related; mean weight loss was 1.1 kg in patients receiving less than 200 mg/day of topiramate and 5.9 kg in patients receiving 800 mg/day or more (Langtry et al. 1997). Weight reduction usually plateaued after 15–18 months of treatment (Rosenfeld et al. 1997b).

DRUG–DRUG INTERACTIONS

Although topiramate is minimally metabolized by the liver, its clearance can be increased by the coadministration of hepatic enzyme–inducing drugs (Bialer et al. 2004; Gidal 2002; Langtry et al. 1997; Rosenfeld et al. 1997a; van Passel et al. 2006). Thus, carbamazepine and phenytoin may substantially decrease topiramate levels. Conversely, topiramate has mild enzyme-inducing properties and may enhance metabolism of ethinyl estradiol. Available data suggest that at topiramate doses of 200 mg/day or lower, this induction is insignificant, but at doses greater than 200 mg/day, induction becomes dose dependent and occurs to a great extent (Bialer et al. 2004). Women taking combination oral contraceptive agents therefore need to be counseled about this potential interaction.

There have been reports of topiramate causing increased lithium levels (Abraham and Owen 2004). This effect appears to be rarely clinically significant. Indeed, pharmacokinetic studies suggest that topiramate may slightly decrease serum lithium concentrations (Bialer et al. 2004).

CONCLUSION

Five controlled monotherapy trials and one adjunctive therapy trial indicate that topiramate is not efficacious in the treatment of acute bipolar mania in adults. However, clinical reports suggest that topiramate may be effective in other aspects of bipolar disorder, including juvenile mania, bipolar depression, "soft" forms of bipolar spectrum disorder, and bipolar disorder with comorbid conditions.

Moreover, placebo-controlled trials suggest that topiramate is efficacious in binge-eating disorder, bulimia nervosa, alcohol dependence, borderline personality disorder, psychotropic-induced weight gain, and obesity. Further controlled clinical trials of topiramate in mood, eating, substance use, and personality disorders are needed to more clearly delineate its role as a psychotropic agent.

Chapter 41. Cognitive Enhancers

COGNITIVE ENHANCERS: INTRODUCTION

Disruption of cholinergic neurotransmission and excitatory amino acids is correlated with the development of cognitive impairment and, specifically, Alzheimer's disease (Mesulam 2004). Multiple mechanisms exist that may account for the progression of cognitive impairment, including those related to cholinesterase, *N*-methyl-D-aspartate, vascular disease, and oxidative damage (Aisen and Davis 1994; Bartus et al. 1982; Behl 1999; Behl et al. 1992; Jick et al. 2000; Kalaria et al. 1996; Selkoe 2000; Terry and Buccafusco 2003; Wolozin et al. 2000). An outcome of the disruption of many neurotransmitter systems, cognitive impairment may occur at any time during the disease process as synaptic plasticity becomes impaired, degrading the efficiency of neuronal transmission (Malik et al. 2007). It is intuitive that the earliest intervention prior to irreversible disease progression is optimal. Currently, it is unknown when the irreversible disease processes begin; no specific markers have been identified that could guide clinicians to initiate prophylactic treatment prior to the development of cognitive or behavioral manifestations.

Cognitive enhancer is a general term that denotes a pharmacological or nutraceutical intervention that improves cognitive functioning in an impaired or normal brain by reversing or delaying underlying neuropathological changes within the brain or by modulating the existing neurochemistry to facilitate a desired performance differential. The molecular pathogenesis of cognitive impairment is not fully understood; thus, an ideal pharmacological agent has been difficult to develop. No single agent developed to date is ideally suited for this task; however, several agents have shown beneficial results. In this chapter, I review the established and the most promising potential cognitive enhancers.

CHOLINESTERASE-RELATED THERAPIES

Impairment of cholinergic neurotransmission, especially in the hippocampus and cerebral cortex, has been clearly established over the last 30 years as a significant factor in the clinical signs of cognitive impairment, including those of Alzheimer's disease (Davies and Maloney 1976; Mesulam 2004; Whitehouse et al. 1982). Butyrylcholinesterase (BChE) and acetylcholinesterase (AChE) are the two main types of cholinesterase present in the brain. The development of AChE inhibitors (AChEIs) to increase acetylcholine levels in the brain for enhanced synaptic transmission has been successful, with marginal positive clinical outcomes to date (Birks 2006; Thompson et al. 2004). Four AChEIs have been marketed in the United States for cognitive therapy: tacrine, donepezil, rivastigmine, and galantamine. These pharmaceuticals are primarily for symptomatic relief and have limited current value in stopping or reversing the disease process, although research into subtle neurotrophic and neuroprotective effects of these agents proceeds (Murphy et al. 2006). A significant number of AChEI nonresponders exists (Jones 2003). Improvements in cognitive functioning have been shown with AChEIs without major differences in their efficacy (Birks 2006; Seltzer 2006; Thompson et al. 2004). The major side effects of AChEIs are gastrointestinal.

Recommendations

Tacrine is no longer recommended for routine clinical use. Donepezil, rivastigmine, and galantamine

are recommended with or without other cognitive enhancers (e.g., memantine) (Table 41–1). Tolerability is improved by slow dosage titration. All cholinesterase inhibitors have significant potential for side effects; it is difficult to determine whether one AChEI has a significantly better side-effect profile than another AChEI given individual patients' variability. Switching AChEIs can be a reasonable treatment strategy if lack of efficacy or tolerability is an issue.

Tacrine

Tacrine, a first-generation AChEI and BChE inhibitor (BChEI), is rarely used today due to its (reversible) hepatotoxicity, drug–drug interactions, and the four-times-daily dosing schedule required to achieve adequate central nervous system concentrations for cognitive enhancement. Tacrine is available in an oral tablet formulation. Dosing begins with 40 mg/day given in four 10-mg doses, with titration upward every 4 weeks by 10 mg per dose to a maximal dosage of 160 mg/day (four 40-mg doses). The use of tacrine requires monitoring of liver enzymes.

Indole-tacrine heterodimers are being developed as dual-site AChEIs that would also inhibit β-amyloid peptide aggregation. Early studies indicated a net reduction of β-peptide plaque formation in an animal model (Muñoz-Ruiz et al. 2005). The simultaneous targeting of multiple receptor sites, reduction of amyloid burden, and other neuroprotective modulations are the major mechanisms of

combination therapy. Combination therapy approaches likely represent the future for the field of cognitive enhancers.

Donepezil

Donepezil, a piperidine-based, reversible, noncompetitive AChEI with a plasma half-life of about 70 hours, was approved for the treatment of mild to moderate Alzheimer's disease in the United States in 1996 and for severe Alzheimer's disease in 2006. Donepezil is given once daily in 5-mg or 10-mg doses; 5-mg therapy is only slightly less effective than 10-mg therapy and can be an appropriate regimen, especially when tolerability is an issue (Birks and Harvey 2006).

Donepezil has shown benefit in treating mild, moderate, and severe Alzheimer's disease (Birks and Harvey 2006; Wallin et al. 2007) and is currently being studied for efficacy in patients with mild cognitive impairment (Chen et al. 2006; Seltzer 2007). A recent meta-analysis of pooled data on the use of donepezil indicated caution is warranted in its use to treat mild cognitive impairment due to modest treatment effects with significant side effects (Birks and Flicker 2006).

In addition to Alzheimer's disease patients, Parkinson's disease, multiple sclerosis, and vascular dementia patients have benefited from donepezil therapy (Aarsland et al. 2002; Black et al. 2003; Blasko et al. 2004; Christodoulou et al. 2006; Leroi et al. 2004; Rowan et al. 2007; Seltzer 2007; Wilkinson et al. 2003). The use of donepezil as pretreatment in electroconvulsive therapy (ECT) has also been studied; patients who received donepezil prior to ECT have shown significantly faster recovery of cognitive deficits in the post-ECT period (Jyoti et al. 2006).

Rivastigmine

Rivastigmine, a carbamyl derivative, is a slowly reversible AChEI and BChEI with an elimination half-life of about 2 hours. It was approved in 2000 for use in the United States to treat mild to moderate dementia of Alzheimer's disease and Parkinson's disease. Rivastigmine inhibits the G1 isoenzyme of AChE selectively up to four times more potently than it does the G4 isoenzyme (Enz et al. 1993). This unique compound with its BChEI properties has been postulated to be of greater benefit than other AChEIs in the treatment of Alzheimer's disease because BChE activity increases in the hippocampus and cortex while AChE activity diminishes (Tasker et al. 2005); to date, this has not been conclusively shown to be of clinical significance. However, as a therapy involving multiple target receptor sites, this agent does have a theoretical advantage over single-target approaches. A rivastigmine skin patch received U.S. Food and Drug Administration approval in 2007; gastrointestinal side effects are reduced in frequency with this drug delivery system.

Rivastigmine is initiated at 1.5 mg taken twice daily; the dosage is increased by 1.5 mg every 2 weeks to a daily maximum of 6–12 mg divided into two doses. Transdermal therapy is initiated at one 4.6-mg skin patch applied daily for at least 4 weeks, at which time the dosage may be increased to the 9.5-mg daily patch.

Galantamine

Galantamine hydrobromide, a tertiary alkaloid, is a specific, competitive, and reversible AChEI with a plasma half-life of 6–8 hours that was first marketed in the United States in 2001 as a treatment of mild to moderate dementia of Alzheimer's disease. Galantamine is unique in that it modulates neuronal nicotinic receptors (Coyle and Kershaw 2001). Whether this nicotinic receptor modulation imparts any significant clinical benefit in disease modification remains unknown. The optimal dosage range is 16–24 mg/day. The extended-release formulation for once-daily dosing has similar efficacy and side effects as the twice-daily dosing formulation. Pooled data from trials in patients with mild cognitive impairment have shown significantly higher rates of death due to bronchial carcinoma/sudden death, cerebrovascular disorder/syncope, myocardial infarction, and suicide in the galantamine treatment groups (Cusi et al. 2007; Loy and Schneider 2006); follow-up studies are under way to clarify these

findings. One double-blind, placebo-controlled trial of galantamine with antipsychotic medication in the treatment of subjects with schizophrenia did not show significant benefit, although the trend was toward improvement in several cognitive domains (Lee et al. 2007).

Other Agents

Physostigmine

Physostigmine, a reversible inhibitor of BChE and AChE, is poorly tolerated due to multiple gastrointestinal side effects, especially nausea and vomiting, and has a very short half-life. Physostigmine is inactivated within approximately 2 hours due to hydrolysis. An evaluation of 15 studies using physostigmine showed only marginal clinical efficacy and significant adverse side effects even with controlled-release formulations (Coelho and Birks 2001).

Huperzine Alpha

Huperzine alpha (more commonly known as huperzine A) is sold in the United States as a dietary supplement for cognitive enhancement. It was first isolated from club moss (*Huperzia serrata*) as a sesquiterpene alkaloid and is a slow, reversible inhibitor of AChE. Huperzine A has been shown to significantly improve memory in Alzheimer's disease patients with only limited side effects to date (Zangara 2003; Z. Zhang et al. 2002). It is believed to have neuroprotective effects by reducing neuronal cell death caused by glutamate (Ved et al. 1997). The combination of other AChEIs with huperzine A may exacerbate gastrointestinal side effects; patients' usage of this over-the-counter supplement should be monitored, especially if other AChEIs are considered for treatment.

Metrifonate

Metrifonate, a long-acting irreversible cholinesterase inhibitor, was tested in clinical trials, but further development was discontinued after a higher-than-expected incidence of neuromuscular dysfunction and respiratory paralysis was found. Metrifonate recipients with Alzheimer's disease showed significant cognitive improvement compared with placebo recipients at most dosages (50–80 mg/day) (Lopez-Arrieta and Schneider 2006).

Nicotinic Receptor Agonists

Selective and nonselective neuronal nicotinic receptor agonists have shown statistically significant cognitive enhancement in young, healthy subjects and in subjects with Alzheimer's disease (Dunbar et al. 2007; Newhouse et al. 1997, 2001; Potter et al. 1999; Sunderland et al. 1988). Some prior research using nicotine skin patches to improve attention in Alzheimer's disease patients has been conducted with limited efficacy shown (White and Levin 1999). Other studies have shown that chronic administration of nicotine using skin patches did improve cognitive functioning in Alzheimer's disease patients (Rusted et al. 2000). The use of selective neuronal nicotinic receptor agonists is an intuitive combination therapy with AChEIs for cognitive enhancement; research continues in this developing area.

N-METHYL-D-ASPARTATE–RELATED THERAPY

Glutamate is an agonist of kainate, *N*-methyl-D-aspartate (NMDA), and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors. Neuronal plasticity of memory and learning is influenced by glutamate's direct modulation of the NMDA postsynaptic receptor; glutamate acts as an excitatory neurotransmitter activating the NMDA receptor. Glutamate excess results in neurotoxicity affecting cognitive functioning (Koch et al. 2005).

Recommendations

Memantine appears to reduce the level of cognitive impairment in patients with moderate to severe

Alzheimer's disease. Memantine in combination with an AChEI is an appropriate consideration for improvement in cognition and behavior.

Memantine

Memantine is a noncompetitive NMDA receptor antagonist approved in the United States for treating moderate to severe Alzheimer's disease. The NMDA receptor modulates memory function. Memantine may prevent neurotoxicity due to its low-affinity antagonism of glutamate, which has been linked to neurodegeneration and excitotoxicity (Lipton and Rosenberg 1994). Memantine has been shown to be effective in reducing the level of cognitive impairment in patients with moderate to severe Alzheimer's disease (Bullock 2006; Reisberg et al. 2003). Memantine is available in tablets and as an oral solution; dosing should be adjusted for patients with moderate or severe renal impairment. It is recommended that memantine be initiated at a dosage of 5 mg/day for 1 week, increasing weekly by 5 mg/day up to a target dosage of 20 mg/day. Memantine is generally given in twice-daily doses, although the elimination half-life ranges from 60 to 80 hours.

Memantine Combination Therapy

Memantine in combination with an AChEI has been shown to improve cognitive domains significantly and to improve behavioral dyscontrol (agitation/aggression, eating/appetite, irritability/lability) (Cummings et al. 2006; Tariot et al. 2004). Given the disruption of multiple neurotransmitter systems and pathways in Alzheimer's disease and other cognitive disorders, the use of adjunctive cognition-enhancing medications is understandable (Grossberg et al. 2006). The specific neurobiological deficit(s) that any pharmacological or nutraceutical intervention may impact should be considered.

VASCULAR AND INFLAMMATION-RELATED THERAPIES

Major known modifiable risk factors for vascular cognitive impairment (with or without dementia) include diabetes mellitus, hypertension, cardiac ischemia, atrial fibrillation, smoking, hyperlipidemia, and peripheral vascular disease (Desmond et al. 1993; Rockwood et al. 1997). Controversial risk factors include hyperhomocysteinemia. Established vascular treatment interventions have included low-dose aspirin and other antiplatelet agents, anticoagulation agents, antihypertensives, aggressive management of diabetes mellitus, carotid endarterectomy for selected patients, and the treatment of hyperlipidemia. There is a significant overlap of patients with vascular cognitive impairment and those with Alzheimer's disease (Gearing et al. 1995; O'Brien 1994). Cholinergic receptors (muscarinic and nicotinic) are known modulators of cerebral blood flow (Schwarz et al. 1999; W. Zhang et al. 1998). Ischemia-induced NMDA stimulation may further cognitive impairment.

A meta-analysis of four randomized, placebo-controlled studies of AChEIs to treat vascular dementia—two with donepezil and two with galantamine—showed statistically significant cognitive enhancement even though the treatment effect was less than what has been observed in Alzheimer's disease patients (Birks and Flicker 2007). In addition, the authors analyzed pooled results from memantine studies and found statistically significant improvement of cognitive functioning with memantine treatment in patients with vascular impairment similar to that seen with the AChEIs (Birks and Flicker 2007). A Cochrane review indicated that donepezil in doses of either 5 mg or 10 mg improves both functional ability and cognitive symptoms in patients with mild to moderate vascular cognitive impairment; donepezil was well tolerated in this analysis (Malouf and Birks 2004). A more recent Cochrane review of the use of galantamine to treat vascular cognitive impairment showed statistically significant results in terms of cognition and executive function with galantamine versus placebo in one study but not in a second study that had fewer subjects; gastrointestinal side effects were noted to be higher in galantamine recipients (Craig and Birks 2006).

Recommendations

AChEIs appear to have a valid role in the treatment of vascular cognitive impairment. Combination

therapy is an important consideration, especially with other known vascular risk modifiers including aspirin, other NSAIDs, and CDP-choline. Randomized, controlled trials do not currently support the use of aspirin or other NSAIDs for the treatment of vascular cognitive impairment. The active use of statins for the prevention and treatment of vascular cognitive impairment is currently not well supported by the literature; however, research with statins remains very active in this pursuit.

Statins

β-Amyloid formation and accumulation may be modulated by cholesterol. The Cardiovascular Health Study results indicated that the use of statins (3-hydroxy-3-methylglutaryl coenzyme A [HMG-CoA] reductase inhibitors) was associated with a decrease in cognitive decline that was not attributed to the lowering of serum cholesterol levels (Bernick et al. 2005). Some epidemiological investigations also suggest that the progression of cognitive decline decreases with statin use (Rockwood et al. 2002; Wolozin et al. 2000). Studies to date are not conclusive about the benefit of statins for the long-term treatment of vascular cognitive impairment, however. In a post hoc analysis of pooled data from three placebo-controlled, double-blind studies of patients with Alzheimer's disease who were treated with galantamine or galantamine plus a statin, galantamine was associated with significant benefits in cognitive functioning, whereas the use of statins and galantamine did not result in a significant improvement, only a small positive improvement (Winblad et al. 2007).

CDP-Choline

Cytidine 5'-diphosphocholine (CDP-choline), or citicoline, has shown mixed results regarding its potential benefit in the treatment of cognitive impairment (Cohen et al. 2003; Secades and Lorenzo 2006). CDP-choline is an intermediate in the production of phospholipids of cell membranes. Impairment in phospholipids leads to cell function loss and has been shown to be a factor in cerebral ischemia (Klein 2000). A Cochrane review of 14 studies indicated a positive benefit of CDP-choline on memory and behavior (Fioravanti and Yanagi 2005). CDP-choline may have antiplatelet aggregation effects and cholinergic modulation effects and may increase dopamine synthesis in selected brain regions (Secades and Lorenzo 2006).

Aspirin

Strong data have not yet emerged supporting the cognitive benefits of aspirin usage to treat vascular cognitive impairment (Kang et al. 2007; Whalley and Mowat 2007). Aspirin remains a cornerstone first-line intervention for decreasing potential cardiovascular comorbidity. As such, aspirin may have a future role as a combination therapy with cognitive enhancers; future longitudinal research will help clarify this position.

Other Nonsteroidal Anti-Inflammatory Drugs

Other nonsteroidal anti-inflammatory drugs (NSAIDs) provide a neuroprotective effect and affect amyloid pathology (H. Hao et al. 2005; Siskou et al. 2007; Weggen et al. 2001). A specific role for their use in the treatment of cognitive impairment has not been well established. Significant gastrointestinal side effects remain a concern for long-term usage. Active research continues on novel anti-inflammatory derivatives that have desired properties with limited side effects (Siskou et al. 2007).

ANTIOXIDANT-RELATED THERAPIES

Antioxidant-related treatment for cognitive impairment remains poorly supported by placebo-controlled, double-blind studies. Although this may be a potential combination therapy modality, further research is required before endorsing specific treatment recommendations with current antioxidants.

Ginkgo Biloba

Ginkgo biloba could be classified within several potential treatment categories, including antioxidants, nutraceuticals, cholinergic agents, and vasodilators. *Ginkgo biloba* extract is currently marketed in the United States as a food supplement. Studies have shown potential benefit in using ginkgo to delay the progression of cognitive impairment or to enhance survival rates in humans and animal models (Andrieu et al. 2003; Dartigues et al. 2007; Naik et al. 2006). A review based on Cochrane meta-analyses showed a significant cognitive benefit of ginkgo only with pooled results (Kurz and Van Baelen 2004). Although the use of ginkgo appears to have a definite positive benefit in patients with cognitive impairment, most studies have shown marginal significance. The recommended dosage range is 120–240 mg/day.

Vitamins and Carotenoids

Vitamin E (including tocopherols and tocotrienols), vitamin C, and carotenoids are accepted agents with known antioxidant properties. Vitamin E is believed to act as a peroxyl radical scavenger. Reports of its benefit in treating patients with cognitive impairment are mixed, with some studies showing a delay in the progression of Alzheimer's disease symptoms (Engelhart et al. 2002; Sano et al. 1997). Vitamin E can affect blood coagulation and has potential cardiovascular side effects. The research on the efficacy of vitamin C as an antioxidant for treating cognitive impairment is currently less supportive. Carotenoids have a potential role as free radical scavengers; however, current research has not shown a significant time delay in the progression of cognitive impairment with their use. Combination therapy for cognitive impairment may well incorporate judicious amounts of vitamins and carotenoids as future research delineates the specific role of these agents in managing free radicals.

OTHER AGENTS

Currently, no recommendations for use of the following agents as monotherapy or combination therapy can be made.

Secretase Inhibitors

The use of secretase inhibitors is one of the approaches to reduce the β-amyloid protein load in the aging brain. The β-amyloid precursor protein is cleaved by proteases; the major proteases are β-secretase and γ-secretase and, to a lesser extent, α-secretase (Hamaguchi et al. 2006).

Mice models using a β-secretase inhibitor have shown reduced levels of β-amyloid protein (Asai et al. 2006). Inhibition of γ-secretase can have an impact on the familial expression of Alzheimer's disease through the genetic influence of presenilin and presenilin-2. However, each of these secretases may impact multiple protein substrates, in which case a nonspecific β- or γ-secretase inhibitor may yield major unwanted side effects (Hamaguchi et al. 2006). Secretase inhibition remains an active area of research and has the potential to have a major impact on the treatment of cognitive impairment.

Tramiprosate

Tramiprosate is a small-molecule glycosaminoglycan compound that inhibits the development of β-amyloid plaque formation, thus reducing neurotoxic effects (Geerts 2004, Molecule of the month 2006). Tramiprosate failed to show significantly better efficacy than placebo in phase III clinical trails. Agents that prevent amyloid production or amyloid aggregation would have great utility in preventing the progression of Alzheimer's disease. Research targeting neuropathological substrates is exploring tau phosphorylation, apoptosis, formation of neurofibrillary tangles, amyloid production, and amyloid aggregation to develop pharmaceuticals with the potential to prevent and treat cognitive impairment, especially Alzheimer's disease.

Modafinil

Modafinil is marketed in the United States as a wakefulness-promoting drug. Minimal cognition-enhancing effects have been noted in low-dose (100-mg) treatment in non-sleep-deprived,

middle-age subjects (Randall et al. 2004). Clinicians have used modafinil for the treatment of apathy associated with Alzheimer's disease. Modafinil is not recommended as monotherapy or in combination therapy for cognitive enhancement based on the current literature.

Hormone Replacement Therapy

Hormone replacement with estrogen-related compounds is not recommended at this time. For women in early perimenopause, hormone replacement therapy may provide an initial benefit for preventing cognitive decline. Once the clinical symptoms of Alzheimer's disease are present, however, studies have shown that estrogen replacement may have negative effects on sustained cognitive performance (Thal et al. 2003). However, recent research in elderly primates indicates that early intervention with estrogen replacement can significantly benefit the structural and functional integrity of key brain sites by enabling synaptic plasticity (J. Hao et al. 2007). Research on the use of hormone replacement therapy for the prevention and treatment of cognitive impairment in perimenopausal women remains active.

Nutraceuticals

To date, randomized, placebo-controlled studies of nutraceutical and herbal treatments for cognitive impairment are limited. Animal studies and limited human studies are of interest but yet not conclusive about the treatments' benefits in humans. Agents of interest include *Rubia cordifolia* root, sage (*Salvia lavandulaefolia*), rosemary (*Rosmarinus officinalis*), and lemon balm (*Melissa officinalis*) (Kennedy and Scholey 2006; Patil et al. 2006). Sage has been shown to improve immediate word recall in healthy young adults (Tildesley et al. 2003). Various compounds found in these agents have been shown to have AChE and BChE inhibitory properties, possess anti-inflammatory and antioxidant properties, and modulate muscarinic and nicotinic receptors (Kennedy and Scholey 2006). L-theanine, an amino acid found in green tea, has shown limited cognition-enhancing effects (Nathan et al. 2006). If further randomized, placebo-controlled studies show even a modest beneficial effect, these agents would have potential in combination therapy for the prevention and treatment of Alzheimer's disease and other types of cognitive impairment. Prior to recommending any of these agents, clarity with regard to the expected target system is important because combination therapy with existing AChEIs could cause profound exacerbation of side effects.

Dehydro-3-Epiandrosterone

Dehydro-3-epiandrosterone (DHEA), including the sulfated ester form, is an adrenal hormone with potential neuroprotective effects and the ability to enhance glutamate's effects. Research results are mixed concerning the potential benefit of DHEA for the treatment of cognitive impairment. Case reports suggest improvement in cognition with DHEA usage. DHEA supplementation has been suggested to have a direct negative effect on cognition (Parsons et al. 2006). A recent Cochrane review of three studies did not find a beneficial effect of DHEA supplementation in a population without dementia; however, the authors noted a need for long-term studies with an adequate number of subjects (Evans et al. 2006). DHEA may have a transient effect on cognitive functioning but not provide sustained cognitive improvement (Wolkowitz et al. 2003).

General Compounds

Aniracetam has been shown to improve cognitive impairment from traumatic brain injury to a rat model even after a delay of up to 11 days (Baranova et al. 2006). Piracetam, a cyclic derivative of γ-aminobutyric acid, has mild beneficial cognitive effects on memory and learning (Winnicka et al. 2005). In animal models, unifiram has been shown to induce acetylcholine release and act as a cognition-enhancing agent (Martini et al. 2005).

Immunomodulatory Agents

Antiamyloid immunization may provide one of the greatest opportunities to prevent β-amyloid deposition. Immunization strategies generally focus on active or passive immunization and direct central nervous system delivery of anti–amyloid beta antibodies. Active immunization with β-amyloid antibodies can reduce plaque formation (Lemere et al. 2006; Solomon 2006). Passive immunization with monoclonal antibodies or preparations of immunoconjugates shows promise for treating cognitive impairment due to Alzheimer's disease and may be safer than active immunization (Geylis and Steinitz 2006; Solomon 2007). Active and passive immunization may cause microhemorrhages, and further research continues to seek safer vaccines. Reversal of plaque load occurred in mutant mice after active immunization with β-peptide (Games et al. 2000; Schenk et al. 1999). However, during early human trials, meningoencephalitis occurred in up to 5% of the subjects, causing the study to be halted. The occurrence of meningoencephalitis may have been caused by excessive cell-mediated immunity (Asuni et al. 2006). Further research into the potential use of vaccine-driven immunomodulatory approaches is warranted.

CONCLUSION

The molecular pathogenesis of nerve cell death remains elusive, especially as it relates to the onset and progression of cognitive impairment. Alzheimer's disease and other types of cognitive impairment represent a wide spectrum of neurosystem dysfunction, and no single treatment modality yet found is sufficient to address the global apoptosis and degeneration that occur. Due to the multiple types of neurochemical and substructure dysfunction occurring in cognitive impairment, multiple-drug interventions will likely be required (Siskou et al. 2007; Sunderland et al. 1992).

Future studies will explore second-messenger modulation, inhibition of the synthesis of β-amyloid using a mimic of the prion protein to inhibit β-secretase cleavage of the amyloid precursor protein, amyloid plaque sheet breakers, AMPA receptor modulators, and the role of σ_1-receptor agonists and selective neuronal nicotinic receptor agonists (Parkin et al. 2007; Rose et al. 2005; Sarter 2006). Currently, the AChEIs and memantine are appropriate choices for slowing the progression of cognitive impairment. Several other promising agents are likely to become available within the next few years.

Chapter 42. Sedative-Hypnotics

SEDATIVE-HYPNOTICS: INTRODUCTION

In this chapter, we examine some of the pharmacological properties of benzodiazepines, barbiturates, and other sedative-hypnotic compounds. Sedative drugs moderate excitement, decrease activity, and induce calmness, whereas hypnotic drugs produce drowsiness and facilitate the onset and maintenance of a state that resembles normal slee in its electroencephalographic characteristics. Although these agents are central nervous system (CNS) depressants, they usually produce therapeutic effects at doses that are far lower than those that cause coma and generalized depression of the CNS.

Some sedative-hypnotic drugs retain other therapeutic uses as muscle relaxants (especially benzodiazepines), antiepileptic agents, or preanesthetic medications. Although benzodiazepines are used widely as antianxiety drugs, whether their effect on anxiety is truly distinct from their effect on sleepiness remains unconfirmed.

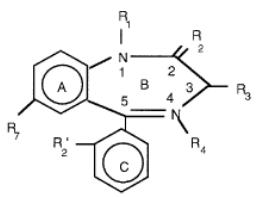
Sedative-hypnotics are also important drugs to neuroscientists. These substances modulate basic behaviors such as arousal and response to stress. With increasing understanding of the molecular structure of the γ-aminobutyric acid type A ($GABA_A$) receptor, the cellular mechanisms of these compounds' mode of action have become elucidated. Further understanding of their mode of action could thus help to elucidate neurochemical and neurophysiological control of these behaviors.

BENZODIAZEPINES

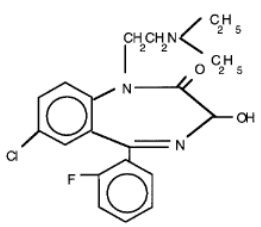
History and Discovery

Benzodiazepines were first synthesized in the 1930s but were not systematically evaluated until 20 years later. The introduction of chlorpromazine and meprobamate, which ha sedative effects in animals, in the early 1950s, led to the decade of development of sophisticated in vivo pharmacological screening methods that were used to identify the sedative properties of benzodiazepines. More than 3,000 benzodiazepines have been synthesized since chlordiazepoxide, which was synthesized by Sterbach in 1957, was introduced into clinical medicine. About 40 of them are in clinical use.

Several drugs chemically unrelated to the benzodiazepines have been shown to have sedative-hypnotic effects with a benzodiazepine-like profile, and these drugs have been determined to act via the benzodiazepine binding site on $GABA_A$ receptor.

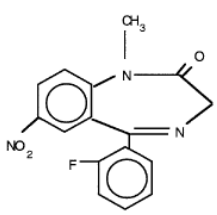


Most of the benzodiazepines currently on the market were selected for their high anxiolytic potential relative to CNS depression. Nevertheless, all benzodiazepines have sedative-hypnotic properties to various degrees, and some compounds that facilitate sleep have been used as hypnotics.



Mainly because of their remarkably low capacity to produce fatal CNS depression, benzodiazepines have displaced barbiturates as sedative-hypnotic agents.

Structure–Activity Relations



The term *benzodiazepine* refers to the portion of the structure composed of benzene rings (*A* in Figure 42–1) fused to a seven-membered diazepine ring (*B*). However, most of the older benzodiazepines contain a 5-aryl substituent (*C*) and a 1,4-diazepine ring, and the term has come to mean 1,4-benzodiazepines.

A substituent (most often chloride) at position 7 is essential for biological activity. A carbonyl at position 2 enhances activity and is generally present. Most of the newest products also substitute the 2 position, as with flurazepam. These general features are important for the metabolic fate of the compounds. Because the 7 and 2 positions of the molecule are resistant to all major degradative pathways, many of the metabolites retain substantial pharmacological activity.

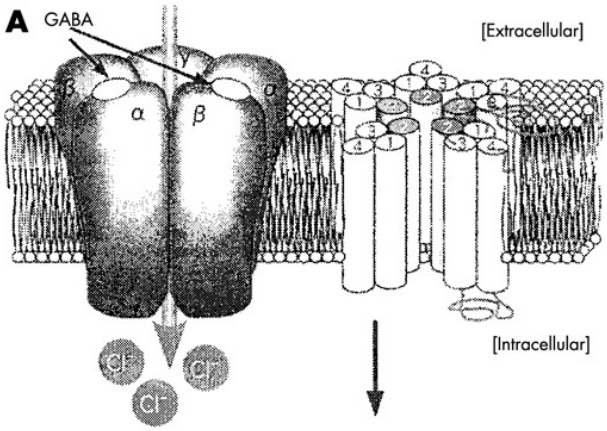
Pharmacological Profile

Benzodiazepines share anticonvulsant and sedative-hypnotic effects with the barbiturates. In addition, they have a remarkable ability to reduce anxiety and aggression (Cook and Sepinwall 1975). In the mammalian CNS, two subtypes of benzodiazepine omega (ω) receptors have been pharmacologically recognized. Benzodiazepine ω_1 (or BZ1) receptors are sensitive to β-carbolines, imidazopyridines (e.g., zolpidem), and triazolopyridazines. Benzodiazepine ω_2 (or BZ2) receptors have low affinity for these ligands and

relatively high affinity for benzodiazepines. Benzodiazepine ω_1 sites are enriched in the cerebellum, whereas ω_2 sites are mostly present in the spinal cord, and both receptor subtypes are found in the cerebral cortex and hippocampus. Benzodiazepine ω_1 and ω_2 receptor subtypes are also located peripherally in adrenal chromaffin cells.

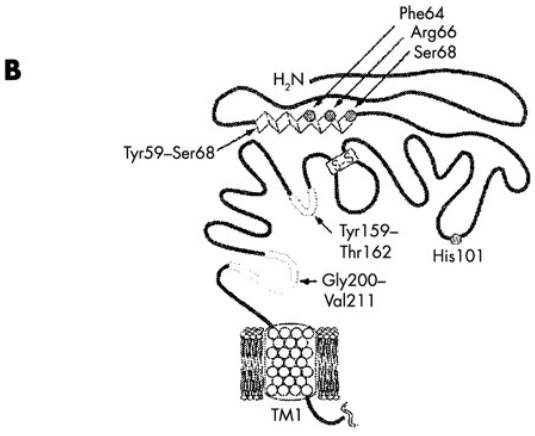
Another subtype, ω_3, was identified and is commonly labeled as the *peripheral benzodiazepine receptor subtype* because of its distribution on glial cell membranes in nonnervou tissues such as adrenal, testis, liver, heart, and kidney. The subtype was later detected in the CNS, especially on the mitochondrial membrane and not in association with $GABA_A$ receptors (Gavish et al. 1992). The ω_3 receptor subtype has high affinity for benzodiazepines and isoquinoline carboxamides (Awad and Gavish 1987). The functional role of this receptor is unknown, but it may be involved in the biosynthesis and mediation of the sedative-hypnotic effects of some neuroactive steroids (pregnenolone, dehydroepiandrosterone [DHEA], allopregnanolone, tetrahydrodeoxycorticosterone) (Edgar et al. 1997; Friess et al. 1996; Rupprecht et al. 1996). Neurosteroids modulate $GABA_A$-mediated transmission through an allosteric mechanism that is distinct from that of benzodiazepines and barbiturates. By stimulation of ω_3 receptors with agonists, cholesterol is transferred from intracellular stores in mitochondria and becomes available to the mitochondrial P450 cholesterol-side-chain-cleavage (P450scc), and neurosteroi biosynthesis begins (Papadopoulos et al. 2001). Benzodiazepine ω_3 receptor subtypes also may serve as mitochondrial membrane stabilizers and protect against pathologically induced mitochondrial and cell toxicity (Papadopoulos et al. 2001).

The $GABA_A$ receptor is a ligand-gated ion channel that mediates fast synaptic neurotransmission in the CNS. When the $GABA_A$ receptor is occupied by GABA or GABA agonists such as muscimol, the chloride channels open and chloride ions diffuse into the cell. Schmidt et al. (1967) first reported that diazepam could potentiate the inhibitory effects of GABA on the spinal cord in cats. Later, it was shown that the effect of diazepam could be abolished if the endogenous content of GABA was depleted. These findings established that diazepam (and related benzodiazepines) did not act directly through GABA but modulated inhibitory transmission through the $GABA_A$ receptor in some other way. It was subsequently reported that benzodiazepines bind specifically to neural elements in the mammalian brain with high affinity and that an excellent correlation exists between drug affinities for these specific binding sites and in vivo pharmacological potencies (Möhler and Okada 1977; Squires and Braestrup 1977).



The binding of a benzodiazepine to this receptor site is enhanced in the presence of GABA or a GABA agonist, thereby suggesting that a functional (but independent) relationshi exists between the $GABA_A$ receptor and the benzodiazepine receptor (Tallman et al. 1978). Barbiturates (and to some extent alcohol) also seem to produce anxiolytic and sedative effects at least partly by facilitating GABAergic transmission (see section "Barbiturates" in this chapter). This common action for chemically unrelated compounds can be explained by the ability of these compounds to stimulate specific sites on the $GABA_A$ receptor.

The benzodiazepines bind with high affinity to their binding sites so that the action of GABA on its receptor is allosterically enhanced. GABA can produce stronger postsynaptic inhibition in the presence of a benzodiazepine. Benzodiazepine agonists are assumed to potentiate only ongoing physiologically initiated actions of GABA (at $GABA_A$ receptors), whereas barbiturates are thought to cause inhibition at all GABAergic synapses regardless of their physiological activity. In addition, barbiturates appear to increase the duratio of the open state of the chloride channel, whereas benzodiazepines increase the frequency of channel openings with little effect on duration (Twyman et al. 1989). These fundamental differences between the allosteric effects of benzodiazepines within the $GABA_A$ receptor and the conducive effects of barbiturates on the chloride ion channel may explain why low doses of barbiturates have a pharmacological profile similar to that of benzodiazepines, whereas high doses of barbiturates cause a profound and sometimes fatal suppression of brain synaptic transmission. Note that selective $GABA_A$ agonists, such as muscimol, have no sedative or anxiolytic properties; thus, the whole $GABA_A$–benzodiazepine receptor complex must be involved to possess sedative-hypnotic properties.



Molecular Mechanism of $GABA_A$–Benzodiazepine Receptor Interaction

The structure of the $GABA_A$–benzodiazepine receptor complex has been elucidated by the cloning of all the implicated subunit genes and the study of the corresponding encoded proteins. The $GABA_A$ receptor is a pentameric protein consisting of five subunits, which forms a rosette surrounding a transmembrane ion channel pore for Cl^- (Figure 42–2). The $GABA_A$ receptor in humans includes the following known subunits: α_1–α_6, β_1–β_4, γ_1–γ_4, δ, ε, π, and θ (7 kinds of subunits, 18 isoforms total) (Mehta and Ticku 1999). Two alternatively spliced versions of the γ_2 subunit, γ_{2S} and γ_{2L}, are also known to exist (Kofuji et al. 1991).

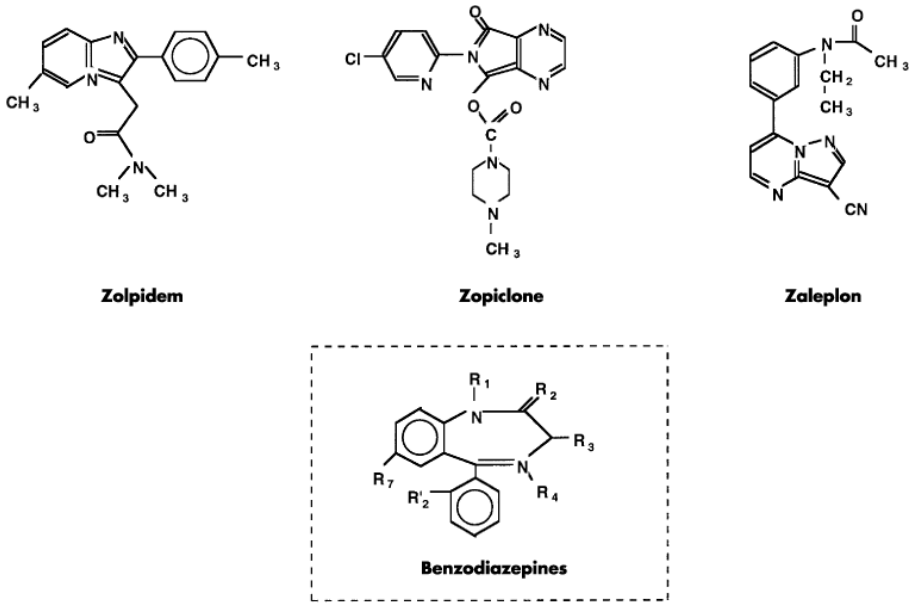
The binding of two molecules of GABA to the action site composed of α and β subunits causes the opening of the chloride channel pore, and the chloride ions diffuse into the cell. Each subunit comprises four transmembrane domains (TM1–TM4). Despite many studies, the physiological and neuroanatomical processes mediating benzodiazepine action on the $GABA_A$ receptor complex remain poorly understood. One reason is that the GABAergic system is the most widespread of all inhibitory neurotransmitters and could be involved in many circuits responsive to various effects of benzodiazepine agonists. In addition, the various subtypes of $GABA_A$ receptor have different ligand affinity and channel functions in response to benzodiazepine agonists. These subtypes of $GABA_A$ are broadly distributed in various brain areas to form a mosaic of receptor subtypes (Wisden and Stephens 1999), making it difficult to understand the functional mechanisms of interaction of benzodiazepine agonists on the $GABA_A$-ergic system from the physiological point of view (Rudolph et al. 1999). However, recent site-directed mutagenesis and gene knock-in techniques have identified several important findings about the benzodiazepine action sites on $GABA_A$ receptors and their physiological functions.



It is postulated that the binding of GABA to *N*-terminal extracellular domains of α and β subunits causes conformational changes within the subunits. Ion channel pores subsequently open, and Cl^- flows across the neuronal membrane, resulting in neuronal inhibition (Amin and Weiss 1993; Boileau et al. 1999; Sigel et al. 1992; Smith and Olsen 1994) (see Figure 42–2). The extracellular domains of the α and γ subunits, which consist of about 220 amino acids in the *N*-terminal region, also have been shown to bind GABA and benzodiazepines. Pharmacologically classified ω_1 and ω_2 receptors are now thought to correspond to $GABA_A$ receptors possessing the α_1 and α_2 subunits and the α_3 and α_5 subunits, respectively.

Extracellular benzodiazepine binding sites on these subunits consist of several divided portions; His101, Tyr159–Thr162, and Gly200–Val211 on α_1 subunits, as well as Lys41–Trp82 and Arg114–Asp161 on γ_2 subunits, are essential to the formation of the binding pockets (Boileau et al. 1998). Most strikingly, His101 is a critical residue for diazepam to exhibit its sedative effect (Crestani et al. 2001; Low et al. 2000; McKernan et al. 2000; Rudolph et al. 1999). Knock-in mice with displacement of His101Arg are insensitive to benzodiazepine-induced allosteric modulation of the complex but have preserved physiological regulation by GABA (Rudolph et al. 1999). These knock-in mice failed to be sedated by diazepam but retained other effects of diazepam, such as anxiolytic-like, myorelaxant, motor-impairing, and ethanol-potentiating effects. This suggests the possibility that the sedative action of the benzodiazepine is mediated through $GABA_A$ receptors possessing the α_1 subunit. It is also noteworthy that His101Arg knock-in mic responded to diazepam and showed similar sleep changes as wild-type mice do, despite the lack of its sedative response in these animals (Tobler et al. 2001). Thus, hypnotic and sedative effects by benzodiazepines may be mediated via different subtypes, with hypnotic effects involving $GABA_A$ receptors possessing subunits other than α_1 (i.e., α_2, α_3 or α_5) (Tobler et al. 2001).

Nonbenzodiazepine Hypnotics (Acting on the Benzodiazepine Receptor)

Until about 1980, it was widely accepted that the benzodiazepine structure was a prerequisite for the anxiolytic profile and for benzodiazepine receptor recognition and binding. However, more recently, three chemically unrelated drugs—the imidazopyridine zolpidem, the cyclopyrrolone zopiclone (and its S[+]-enantiomer, eszopiclone), and the pyrazolopyrimidine zaleplon—have been shown to be useful sedative-hypnotics with benzodiazepine-like profiles (Figure 42–3). Other chemical classes of drugs that are structurally dissimilar to the benzodiazepines (e.g., triazolopyridazines) but act through the benzodiazepine receptor also have been developed and have anxiolytic activity in humans.

FIGURE 42–3. Three nonbenzodiazepine hypnotics—zolpidem (an imidazopyridine), zopiclone (a cyclopyrrolone), and zaleplon (a pyrazolopyrimidine)—have been shown to be useful sedative-hypnotics with benzodiazepine-like profiles.

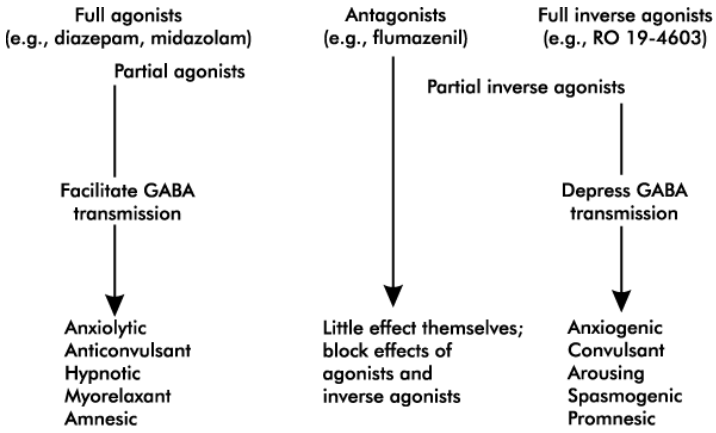
Nonbenzodiazepine hypnotics have a pharmacological profile slightly different from that of classic benzodiazepines. For example, zolpidem binds selectively to ω_1 (the 50% inhibitory concentration [IC_{50}] ratio for ω_1/ω_2 is nearly 1:10) and has sedative-hypnotic properties relative to other properties such as anxiolytic activity or muscle relaxation. Zolpidem and zopiclone have short half-lives (3 hours and 6 hours, respectively). These drugs were originally thought not to appreciably affect the rapid eye movement (REM) sleep pattern, whereas the quality of slow-wave sleep (SWS) may be slightly increased (Jovanovic and Dreyfus 1983; Shlarf 1992). Rebound effects (insomnia, anxiety), which are commonly seen following withdrawal of short-acting benzodiazepines, are minimal for zolpidem and zopiclone. These compounds also induce little respiratory depression and have less abuse potential than common clinical benzodiazepine hypnotics. However, much longer clinical trials are needed to show whether the imidazopyridines or cyclopyrrolones have any significant advantages over the short- to medium-half-life benzodiazepines in the treatment of insomnia. Eszopiclone, the active stereoisomer of zopiclone with longer half-life, was recently approved by the U.S. Food and Drug Administration (FDA). The drug was claimed to help for sleep maintaining as well as for sleep induction. Because the compound induces little tolerance, it is suitable for long-term use.

Zaleplon (*N*-[3-(3-cyanopyrazolo[1,5-a]pyrimidin-7-yl)phenyl]-*N*-ethylacetamide), a pyrazolopyrimidine, also has been developed as a novel nonbenzodiazepine hypnotic (see Figure 42–3). Clinical trials have shown that zaleplon is a well-tolerated, safe, rapidly acting, and effective sedative with advantages over lorazepam with respect to unwanted cognitive and psychomotor impairments (Allen et al. 1993; Beer et al. 1994).

Thanks to an increased understanding of the molecular structure of the $GABA_A$ receptor and its functional correlates, several pharmaceutical companies are also currently developing subtype-selective $GABA_A$ receptor agonists, such as for ω_1, ω_3, and α_4 (selective extrasynaptic $GABA_A$ receptor agonist) subtypes. Preclinical and clinical studies of



these compounds suggested hypnotic effects, and hypnotic uses of some of these are likely to be approved within few years.

Benzodiazepine Antagonists, Partial Agonists, and Inverse Agonists

As knowledge of the relation between the structure of benzodiazepine receptor ligands and their pharmacological properties has increased, potent receptor agonists that stimulate the receptor and produce pharmacological effects qualitatively similar to those of classic benzodiazepines have been developed. ***Antagonists,*** which block the effects o the agonists without having any effects themselves, and ***partial agonists,*** drugs that have a mixture of agonistic and antagonistic properties, also have been introduced (Haefley 1988). Partial agonists may be particularly important to develop in the future as sedative-hypnotics that lack common side effects such as ataxia and amnesia.

At the molecular level, benzodiazepine ***agonists*** are defined as drugs that induce a conformational change in the receptor that produces functional consequences in terms of cellular changes, whereas ***antagonists*** occupy only the binding site. Braestrup and Nielsen (1986) found that a group of nonbenzodiazepine compounds, the β-carbolines, not only antagonized the action of the full agonists but also had intrinsic activity themselves. These compounds are called ***benzodiazepine inverse agonists*** because they have biological effects exactly opposite to those of the pure agonists while also having intrinsic activity like that of agonists. Their effects are blocked by antagonists; thus, the benzodiazepine receptor is particularly unique in that it has a bidirectional function (Figure 42–4).

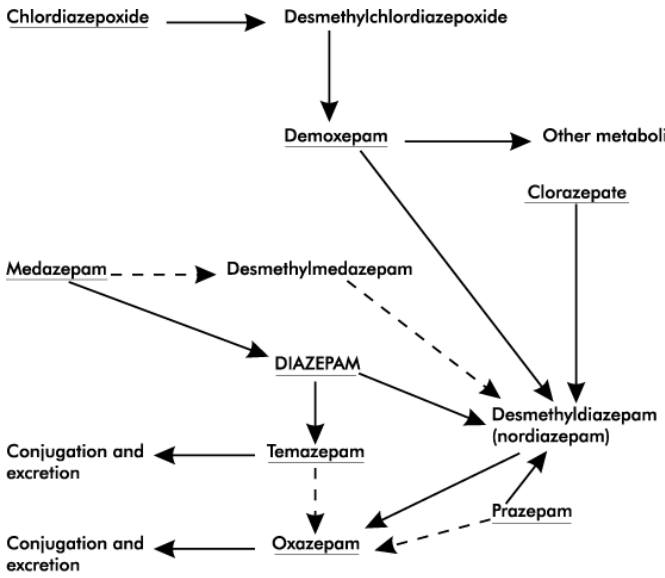
Natural Ligands for Benzodiazepine Receptors in the Brain

The presence of benzodiazepine receptors in the brain suggests that natural ligands modulate GABAergic transmission through these sites. Small amounts of benzodiazepines, such as diazepam and desmethyldiazepam, can be detected in human and animal tissues. This finding was confirmed with human brain tissue samples that had been stored since the 1940s before the first synthesis of benzodiazepines (see Sangameswaran et al. 1986 for details). These benzodiazepines most likely originate from plants, such as wheat, corn, potatoes, or rice, and the levels that are detected are too low to be pharmacologically active (e.g., diazepam, <1 ng/g; desmethyldiazepam, 0.5 ng/g).

Other endogenous benzodiazepine-like substances with neuromodulatory effects probably exist in mammals. Endogenous ligands named ***diazepam binding inhibitors,*** or ***endozepines,*** that bind to the benzodiazepine site on the $GABA_A$-ergic receptor complex have been identified and are being isolated with biochemical purification protocols (Costa and Guidotti 1991; Marquardt et al. 1986; Rothstein et al. 1992). Their intrinsic action, like that of diazepam, is to potentiate $GABA_A$ receptor–mediated neurotransmissio by acting as positive allosteric modulators of this receptor. Endozepines are present in the brain at pharmacologically active concentrations and may play a role both physiologically (e.g., regulation of memory, sleep, and learning) and pathologically (e.g., in panic attacks or hepatic encephalopathy) (Mullen et al. 1990; Nutt et al. 1990). Finally, endozepines have been involved in a newly described neurological condition, ***idiopathic recurring stupor,*** which is characterized by recurrent episodes of stupor or coma in the absence of any known toxic, metabolic, or structural brain damage. In this condition, the concentrations of endozepines are greatly increased in the plasma of affected individuals, and stupor can be interrupted by injections of flumazenil, a benzodiazepine antagonist. Thus, further knowledge of the roles of endozepines in physiological and pathological processes should be forthcoming once these endogenous ligands have been isolated and characterized (Rothstein et al. 1992).



Pharmacokinetics and Disposition

Benzodiazepines are generally absorbed rapidly and completely. Plasma binding is high (e.g., about 98% for diazepam). Benzodiazepines are very lipophilic (except for oxazepam), and penetration into the brain is rapid. For rapid onset of action, diazepam is available as an emulsion that is administered intravenously for rapid control of epilepsy; midazolam is a water-soluble benzodiazepine suitable for intravenous injection.

The major metabolic pathways for the 1,4-benzodiazepines are shown in Figure 42–5. Medazepam is metabolized to diazepam, which is *N*-desmethylated to desmethyldiazepam Chlordiazepoxide is also partly converted to desmethyldiazepam. Clorazepate is transformed to desmethyldiazepam.

Desmethyldiazepam is a critical metabolite for biological activity because of its long half-life of more than 72 hours. Because diazepam's half-life is about 36 hours, the concentration of its desmethyl derivative soon exceeds that of diazepam during chronic administration. Desmethyldiazepam undergoes oxidation to oxazepam, which (like its 3-hydroxy analog temazepam) is rapidly conjugated with glucuronic acid and excreted.

FIGURE 42–5. Metabolic pathways for the principal 1,4-benzodiazepines.

Solid and *broken arrows* denote major and minor pathways, respectively; commercially available drugs are underscored. Flurazepam, flunitrazepam, nitrazepam, and triazolam have separate metabolic pathways.

Among the various benzodiazepines, triazolam has a particularly short half-life (<4 hours), and flurazepam and nitrazepam both have long half-lives (see Table 42–2 later in thi chapter). A major active metabolite of flurazepam, *N*-desalkylflurazepam, has a very long half-life of about 100 hours.

Because benzodiazepines are often prescribed for long periods, their long-term pharmacokinetics are particularly important. Concentrations of diazepam and desmethyldiazepam reach a plateau after a few weeks. Diazepam concentrations may then decline somewhat without much change in the concentration of the desmethyl metabolite.

Although benzodiazepines can stimulate liver metabolism in some animals, induction is of little clinical significance in humans.

Regarding the pharmacokinetics of nonbenzodiazepine hypnotics, no (or only weak) active metabolites exist for the compounds currently available (Table 42–1).

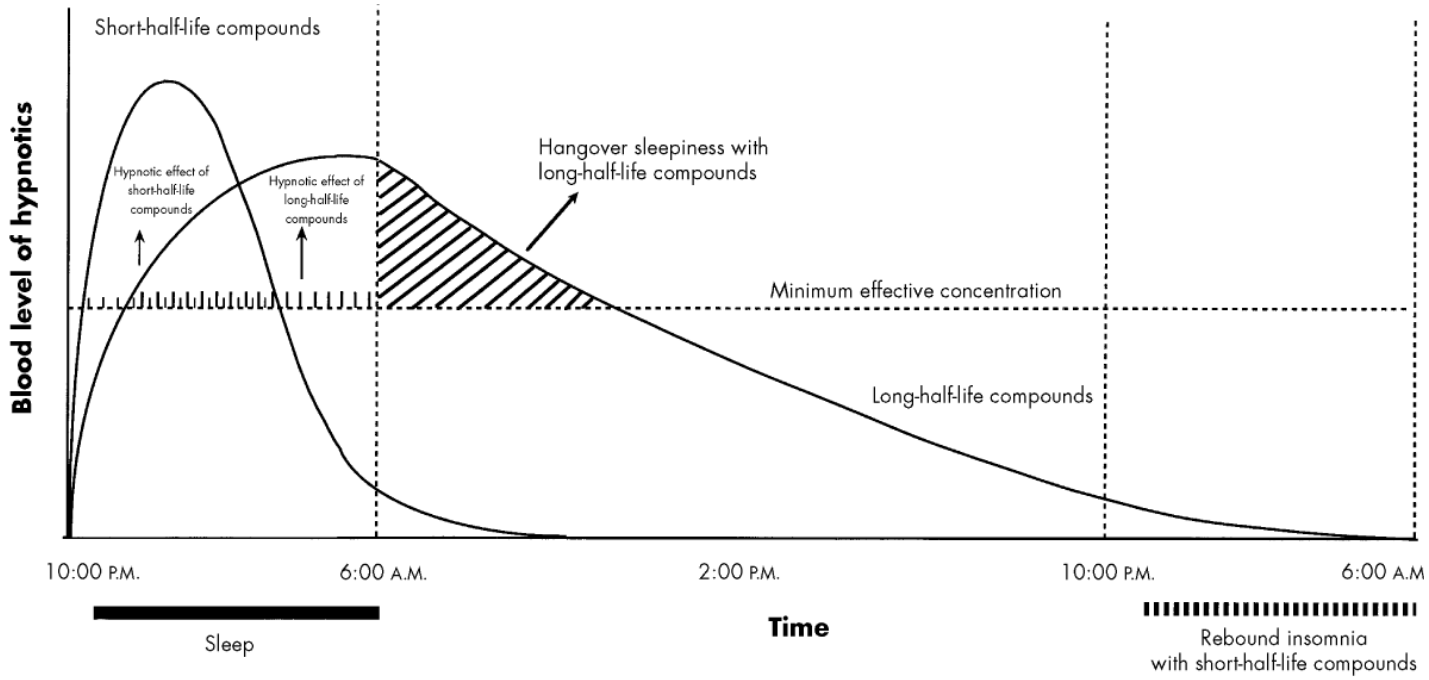
Effects on Stages of Sleep

The hypnotic effects of benzodiazepines (and nonbenzodiazepine hypnotics described in this section) have been suggested to result from the inhibitory effects of the GABAergic system on the raphe and locus coeruleus monoaminergic ascending arousal systems, but this hypothesis may only partially explain their action. Magnocellular regions of the basal forebrain and the preoptic areas have been recognized as important sites for SWS regulation (Szymusiak 1995). Neurons that are selectively active during SWS have been described in these structures, most typically in the ventrolateral preoptic areas (Saper et al. 2001; Sherin et al. 1996). These neurons contain GABA and galanin, an inhibitory peptide, and project to the main components of the ascending arousal system, such as the raphe and locus coeruleus and brain stem cholinergic nuclei (Saper et al. 2001). The ventrolateral preoptic nucleus also sends a dense inhibitory projection to the tuberomammillary histaminergic nucleus, another important wake-promoting system (see Saper et al. 2001; Sherin et al. 1996). Benzodiazepines may thus indirectly modulate these wake-active monoaminergic neurotransmission to promote their hypnotic effects.

Another important site of action for benzodiazepines might be the suprachiasmatic nucleus (SCN). In SCN-lesioned animals, benzodiazepine treatment does not induce sleep (Edgar et al. 1993), but the hypnotic effect is restored if the SCN-lesioned animal is sleep deprived before drug administration. Benzodiazepines thus may facilitate the release o a sleep debt accumulated during wakefulness rather than produce de novo sleep (Mignot et al. 1992).



The effects of benzodiazepines on sleep architectures are well known. Most benzodiazepines decrease sleep latency, especially when first used, and diminish the number of awakenings (see Table 42–1). All benzodiazepines increase time spent in stage 2 sleep. Benzodiazepines also affect the quality of the SWS pattern. Thus, stages 3 and 4 sleep are suppressed and remain so during the period of drug administration. The decrease in stage 4 sleep is accompanied by a reduction in nightmares.

Most benzodiazepines increase REM latency. The time spent in REM sleep is usually shortened; however, the reduction in percentage of REM sleep is minimal because the numbe of cycles of REM sleep usually increases late in the sleep time. Despite the shortening of SWS and REM sleep, the net effect of administration of benzodiazepines is usually an increase in total sleep time, so that the individual feels that the quality of sleep has improved. Furthermore, the hypnotic effect is greatest in subjects with the shortest baseline total sleep time.

If the benzodiazepine is discontinued after 3–4 weeks of nightly use, a considerable rebound in the amount and density of REM sleep and SWS may occur. However, this is not a consistent finding.

Because long-acting benzodiazepine hypnotics impair daytime performance and increase the risk of falls in geriatric patients, several shorter-acting compounds have been introduced and are the preferred choice for elderly patients (see section "General Considerations in the Pharmacological Treatment of Insomnia" later in this chapter). However, it has since been found that short-acting benzodiazepines induce rebound insomnia (a worsening of sleep difficulty beyond baseline levels on discontinuation of a hypnotic) (Kales et al. 1979), rebound anxiety, anterograde amnesia, and even paradoxical rage (Figure 42–6). Many other factors, such as the subtype of insomnia being treated and the dosage and duration of treatment, are also important in explaining the occurrence of these specific side effects that may also be observed with other benzodiazepines. Nevertheless, enthusiasm for shorter-acting compounds has been tempered.

Hypnotics with long half-lives may impair daytime performance the day after drug administration, whereas short-acting compounds may induce rebound insomnia on discontinuation.

Indications and Efficacy

Benzodiazepines are the drug treatment of choice in the management of anxiety, insomnia, and stress-related conditions. Although none of the currently available compounds have any significant advantage over the others, some drugs can be selected to match the patient's symptom patterns to the pharmacokinetics of the various drugs. If a patient has a persistently high level of anxiety, one of the precursors of desmethyldiazepam such as diazepam or clorazepate is most appropriate. Patients with fluctuating anxiety may prefer to take shorter-acting compounds, such as oxazepam or lorazepam, when stressful circumstances occur or are expected. The indications of nonbenzodiazepine hypnotics are equivalent to those of benzodiazepine hypnotics but may be more specific depending on the pharmacological property of each compound.

An ideal hypnotic should induce sleep rapidly without producing sedation the next day. Both flurazepam and nitrazepam have inappropriately long half-lives as hypnotics unless a persistent anxiolytic effect is desired the next day (see Figure 42–6). Even in such situations, diazepam given as one dose at night may be preferable. Oxazepam penetrates too slowly for a dependable hypnotic effect (slow onset of action). Both lorazepam and temazepam are appropriate treatments for insomnia, but the dosages available are quite high (Table 42–2). Triazolam is the shortest-acting hypnotic available. When very small doses of benzodiazepines (which were assumed to have no significant hypnotic action) are administered to patients with insomnia, sleep quality often improves greatly, and usually it is not necessary to use a benzodiazepine at a hypnotic dose as a first-choice treatment.

Benzodiazepines can increase the frequency of apnea and exacerbate oxygen desaturation in healthy subjects and in subjects with chronic bronchitis (Geddes et al. 1976). Although many reports suggest that benzodiazepines are safe in patients with obstructive sleep apnea, other authors disagree, and it seems wise to avoid hypnotics in patients with severe sleep apnea. One of the only other contraindications is myasthenia gravis, a condition in which muscle relaxation with benzodiazepines can exacerbate muscle atonia.

Benzodiazepines have many indications other than sleep induction and anxiolysis, such as epilepsy (see Chapter 24, "Benzodiazepines"). Lorazepam and diazepam can be used for relaxation procedures, preoperative medication, and sedation during minor operations and investigations, often causing retrograde amnesia, a side effect that is sometimes desirable in this indication. Benzodiazepines have been used to manage alcohol withdrawal because cross-tolerance usually exists with alcohol, but large doses are often needed to suppress the withdrawal syndrome.

Side Effects and Toxicology

When a benzodiazepine is taken at high doses, tiredness, drowsiness, and profound feelings of detachment are common but can be minimized by a careful dose adjustment. Headache, dizziness, ataxia, confusion, and disorientation are less common except in the elderly. A marked potentiation of the depressant effect of alcohol occurs. Other less common side effects include weight gain, skin rash, menstrual irregularities, impairment of sexual function, and, very rarely, agranulocytosis.

Although otherwise asymptomatic subjects clearly show mental impairment with benzodiazepines, the situation with anxious patients is more complex. Because anxiety itself interferes with mental performance, alleviation of anxiety may result in improved functioning, which more than compensates for the direct drug-related decrement. The effects in some patients may be complicated and unpredictable, even at low dosages.

Because the safety of benzodiazepines in early pregnancy is not established, they should be avoided unless absolutely necessary. Diazepam is secreted in breast milk and may make the infant sleepy, unresponsive, and slow to feed.

Overdose

The benzodiazepines are extremely widely prescribed, so it is not surprising that they are used in many suicide attempts. For adults, overdoses of benzodiazepines reportedly are not fatal unless alcohol or other psychotropic drugs are taken simultaneously. Typically, the patient falls asleep but is arousable and wakes after 24–48 hours. Treatment is supportive. A stomach pump is usually more punitive than therapeutic, and dialysis is usually useless because of high plasma binding.

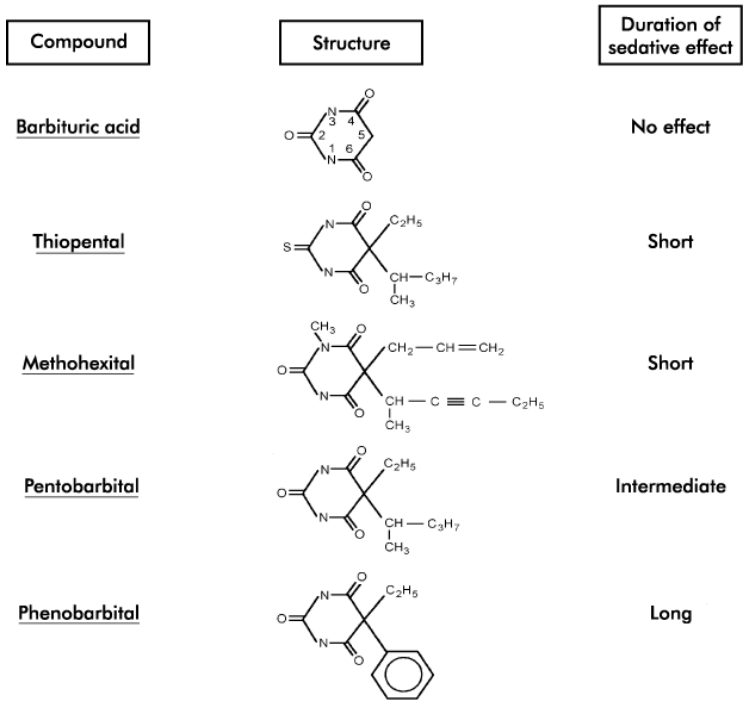
Tolerance and Dependence

Dependence, both psychological and physical, occurs with benzodiazepines as with other sedative-hypnotics. Abrupt discontinuation results in withdrawal phenomena such as anxiety, agitation, restlessness, and tension, which are usually delayed for several days because of the long half-life of the major metabolite, desmethyldiazepam. Even with the normal dose, some patients have withdrawal effects. The fact that some patients gradually increase the dose suggests tolerance, but increases in dose are sometimes related to particularly stressful crises.

Psychological dependence is also common, based on the high incidence of repeated prescriptions, but it is mild, and the drug-seeking behavior is much less persistent than with barbiturates.

BARBITURATES

History and Discovery



Before 1900, a few agents, such as bromide, chloral hydrate, paraldehyde, urethane, and sulfonal, were used as sedatives and hypnotics. Barbital, one of the derivatives of barbituric acid, was introduced in 1903 and soon became extremely popular in clinical medicine because of its sleep-inducing and anxiolytic effects (Maynert 1965). In 1912, phenobarbital was introduced. In addition to its use as a sedative-hypnotic, phenobarbital has become one of the most important pharmacological treatments for epilepsy. Since then, more than 2,500 barbiturate analogs have been synthesized, about 50 of which have been made commercially available and only 20 of which remain on the market.

The success of the partial separation of anticonvulsant from sedative-hypnotic properties led to the development of nonsedative anticonvulsants such as phenytoin in the late 1930s and trimethadione in the early 1940s. The success of barbiturates as sedative-hypnotics was largely overshadowed by the discovery of benzodiazepines in the late 1960s With pharmacological properties very similar to those of barbiturates, these compounds have a much safer pharmacological profile. Thus, benzodiazepines have replaced barbiturates in many incidents, especially for psychiatric conditions in which suicide is a possibility.

Structure–Activity Relations

Barbituric acid (2,4,6-trihexahydroxypyrimidine) is the parent compound of all barbiturates. This basic structure lacks CNS depressant activity, and the addition of two alkyl groups at position 5 is needed to confer sedative activity (Figure 42–7).

The barbituric acid derivatives do not dissolve readily in water but are quite soluble in nonpolar solvents, a feature shared with most other organic compounds that depress the CNS. In general, structural changes that increase liposolubility also decrease these compounds' duration of action, decrease latency to onset of activity, accelerate metabolic degradation, and often increase hypnotic potency.

Derivatives with large aliphatic groups at position 5 have greater activity than do those with methyl groups but shorter duration of action. However, groups with more than seve carbons lose their hypnotic activity and tend to exhibit convulsant activity. Methylation of the 1 *N* atom increases liposolubility and shortens duration of action, and desmethylation may increase the duration of action (Rall 1990).

Pharmacological Profile and Mechanism of Action

The main effects of barbiturates are sedation, sleep induction, and anesthesia. Some of the barbiturates, such as phenobarbital, also have selective anticonvulsant properties. The mechanisms of action of barbiturates are complex and still not fully understood. Nonanesthetic doses of barbiturates preferentially suppress polysynaptic responses. Pertinent to their sedative-hypnotic effects is the fact that the mesencephalic reticular activating system is extremely sensitive to these drugs (Killam 1962). The synaptic site o inhibition is either postsynaptic (e.g., at the level of cortical and cerebellar pyramidal cells and in the cuneate nucleus, substantia nigra, and thalamus relay neurons) or presynaptic (e.g., in the spinal cord). This inhibition occurs only at synapses where physiological inhibition is GABAergic but not glycinergic or monoaminergic. Thus,

barbiturates, like benzodiazepines, specifically potentiate GABA-mediated inhibitory processes in the brain. However, it remains unclear whether all of the effects of barbiturate are entirely mediated by GABAergic mechanisms.

Barbiturates do not displace benzodiazepines from their binding sites; instead, barbiturates enhance benzodiazepine binding by increasing the affinity of the receptor for benzodiazepines (Leeb-Lundberg et al. 1980). They also enhance the binding of GABA and its agonists to specific binding sites (Asano and Ogasawara 1981). These effects are almost completely dependent on the presence of chloride or other anions that are known to permeate the chloride channels associated with the GABA receptor complex, and they are competitively antagonized by picrotoxin (a convulsant) (Olsen et al. 1978). Taken together, these observations suggest that the macromolecular complex composed of $GABA_A$-ergic receptors, chloride ionophores, and binding sites for benzodiazepines (ω site) is also an important site of action for a depressant.

Although both barbiturates and benzodiazepines can potentiate the GABA-induced increase in chloride conductance, barbiturates appear to increase the duration of the open state of chloride channels that are regulated by $GABA_A$-ergic receptors. In contrast, benzodiazepines increase the frequency of channel openings with little effect on the duration. Barbiturates may prolong the activation of the channel by acting directly on the ion channel (Enna and Möhler 1987; Richter and Holman 1982).

The molecular correlations of the barbiturate-acting sites on the $GABA_A$ receptor are also studied. The Tyr-Gly-Tyr sequence in the β subunit is undoubtedly important for the binding of GABA and other direct receptor agonists (Amin and Weiss 1993), as is Phe64 in the α_1 subunit (Smith and Olsen 1995). However, neither the Tyr-Gly-Tyr sequence in β, the Phe64 sequence in α, nor the His101 sequence (which is important for the action of benzodiazepines) in α is of vital importance to barbiturate function (Amin and Weiss 1993). Some reports suggest that the β subunit alone may form a site for barbiturates (Sanna et al. 1995). Although there is still much to be known, new molecular experimenta approaches hold great promise for resolving the most important pharmacological questions regarding which molecular species are important for the anticonvulsant, sedative, anesthetic, and toxic actions of the barbiturates.

Pharmacokinetics and Disposition

For hypnotic use, barbiturates usually are administered orally. Barbiturates are rapidly absorbed in the stomach, and their absorption decreases when the stomach is full. Because sodium salts are rapidly dissolved, they are more rapidly absorbed than free acids.

Barbiturates are metabolized mainly in the liver. Oxidation of the larger of the two side chains at position 5 is a major catabolic pathway. It generally produces inactive polar metabolites that are rapidly excreted in the urine (Rall 1990). Changes in liver function can markedly alter the rate at which these compounds are inactivated. Chronic administration leads to pharmacokinetic tolerance, even when low or infrequent doses of barbiturates are used (see section "Drug–Drug Interactions" later in this chapter).

The rate of penetration of barbiturates into the CNS varies according to their lipophilicity. In general, liposolubility decreases latency to onset of action and duration of action. Thiopental, for example, enters the CNS rapidly and is used to rapidly induce anesthesia; barbitone crosses into the brain so slowly that it is inappropriate as a hypnotic drug.

Effects on Stages of Sleep

Barbiturates decrease sleep latency; however, they also slightly increase fast electroencephalogram (EEG) activity during sleep. Barbiturates decrease body movement during sleep. Stage 2 sleep increases, whereas stage 3 and stage 4 SWS generally decreases, except in some patients with anxiety and in patients who are addicted to barbiturates (se Table 42–1). REM sleep latency is prolonged, and both the total time spent in REM sleep and the number of REM cycles are diminished. With repeated nighttime administration of barbiturates, drug tolerance to the effects on sleep occurs in a few days. Discontinuation of barbiturates may lead to insomnia and disrupted sleep patterns (with a decrease in stage 2 sleep) and increases in REM sleep (Kay et al. 1976).

Indications and Efficacy

Although clinical trials have shown that the barbiturates have sedative and hypnotic properties, barbiturates generally compare poorly with benzodiazepines. The patient feels "drugged" the next day, and there is always the risk of fatal overdose because of the depressant effect on respiration. Barbiturates suppress respiration, and the therapeutic dose of barbiturates may cause fatal respiratory depression in patients with sleep apnea. Patients with sleep apnea should therefore avoid taking barbiturates. Because of these risks, many clinicians have stopped using barbiturates as hypnotics and sedatives (one exception is in the treatment of severe psychomotor excitation) and prescribe them only as anticonvulsants.

Barbiturates also have been administered intravenously to facilitate patient interviews (i.e., amobarbital interview). This technique is also helpful in 1) mobilizing the stuporous catatonic patient, 2) aiding the diagnosis of intellectual impairment, and 3) lessening disturbance associated with previous negative experiences (i.e., abreactions).

Barbiturates are contraindicated in patients with porphyria because they enhance porphyrin synthesis. Liver function should be checked before and during drug administration. Liver dysfunction can significantly prolong the sedative effects of these drugs and may lead to fatal overdose.

Side Effects and Toxicology

In treating many patients who are prescribed barbiturates, it is difficult to control symptoms without causing oversedation. Patients typically oscillate between anxiety and torpor. Mental performance is often impaired, and patients should not drive or operate dangerous machinery.

Patients whose conditions have been stabilized for years with barbiturates must be considered drug dependent. Withdrawal leads to anxiety, agitation, trembling, and, frequently, convulsions. Substitution with a benzodiazepine that can be withdrawn more easily later is often successful.

In some patients, barbiturates repeatedly produce excitement rather than depression (paradoxical excitement), and the patients may appear to be intoxicated.

Hypersensitive reactions (especially of the skin) may occur, and cases of megaloblastic anemia have been reported.

Overdose

An overdose of barbiturates leads to fatal respiratory and cardiovascular depression. Suicide attempts frequently involve overdoses of barbiturates, taken either alone or in combination with alcohol or other psychotropic drugs, particularly tricyclic antidepressants. These suicide attempts, unfortunately, are often successful. Depending on local factors such as proximity to a hospital and expertise of staff for intensive emergency care, death occurs in 0.5%–10% of these cases. Severe poisoning results at 10 times the hypnotic dose, and twice that amount may be fatal.

Tolerance and Dependence

Tolerance to barbiturates occurs rapidly and is a result of both pharmacokinetic factors (e.g., liver enzyme induction) and pharmacodynamic factors (e.g., neuronal adaptation t chronic drug administration). Cross-tolerance develops to alcohol, gas anesthetics, and other sedatives, including benzodiazepines.

Psychological dependence (i.e., drug-seeking behavior) is common. Patients typically visit several physicians to obtain more barbiturates. Physical dependence may be induced by dosages of 500 mg/day. Intoxication may occur, as evidenced by impaired mental functioning, emotional instability, and neurological signs. Abrupt discontinuation after high doses is likely to induce convulsions and delirium. After normal doses, withdrawal phenomena include anxiety, insomnia, restlessness, agitation, tremor, muscle twitching, nausea and vomiting, orthostatic hypotension, and weight loss.

Drug–Drug Interactions

Barbiturates used with other CNS depressants can cause severe depression. Ethanol is the drug most frequently used, and interactions with antihistaminic compounds are also common. Monoamine oxidase inhibitors and methylphenidate also increase the CNS depressant effect of barbiturates.

Barbiturates may increase the activity of hepatic microsomal enzymes two- to threefold. Clinically, this change is particularly important for patients who are also receiving metabolic competitors such as warfarin or digitoxin, for which careful control of plasma concentrations is vital (Rall 1990).

OTHER SEDATIVE-HYPNOTIC COMPOUNDS

Alcohol-Type Hypnotics and Gamma-Hydroxybutyrate

The alcohol-type hypnotics include the chloral derivatives, of which chloral hydrate, clomethiazole, and ethchlorvynol are still used occasionally in the elderly. Chloral hydrate is metabolized to another active sedative-hypnotic—trichloroethanol. These drugs have short half-lives (about 4–6 hours) and decrease sleep latency and number of awakenings; SWS is slightly depressed, but overall REM sleep time is largely unaffected. Chloral hydrate and its metabolite have an unpleasant taste and frequently cause epigastric distress and nausea. Undesirable side effects include light-headedness, ataxia, and nightmares. Chronic use of these drugs can lead to tolerance and occasionally to physical

dependence. As with barbiturates, overdosage can lead to respiratory and cardiovascular depression, and therapeutic use of these drugs has largely been superseded by the us of benzodiazepines.

γ-Hydroxybutyrate (GHB) is a hypnotic agent that has been used mostly in the treatment of insomnia in narcoleptic patients (Scrima et al. 1990). It is rarely used in other indications and is frequently abused by athletes because of its SWS-promoting effects, with resulting increases in growth hormone secretion (Chin et al. 1992); it is also abused because of its euphoric effects (Chin et al. 1992). GHB was classified as a schedule I controlled substance in March 2000 in the United States, but in July 2002, its sodium salt form, sodium oxybate (Xynem), was approved for the treatment of narcolepsy. Nighttime administration of GHB reduces excessive daytime sleepiness associated with narcolepsy. Although the compound is structurally related to GABA, its mode of action involves specific non-GABAergic binding sites and a potent inhibitory effect on dopaminergic transmission (Vayer et al. 1987). The compound promotes SWS and REM sleep (Lapierre et al. 1990), but its effects on sleep architecture are short-lasting, and repeated administration usually is necessary during the night. GHB is also used for the treatment of cataplexy of narcolepsy, but the mechanisms of GHB's effect on cataplexy remain unknown.

Antihistamines

Antihistamines, such as promethazine, diphenhydramine, and doxylamine, are sometimes prescribed as sleep inducers. They decrease sleep latency but do not increase total sleep time (see Reite et al. 1997). These compounds are especially useful for patients who cannot sleep well because of acute allergic reactions or itching. Sedative antihistamines also may be prescribed for those persons who tend to abuse psychoactive drugs, because sedative antihistamines have not been shown to have abuse potential. Rapid tolerance is a problem.

In April 2008, the FDA approved the filing of a new drug application for doxepin hydrochloride, a tricyclic antidepressant with histaminergic$_1$ (H_1) antagonism, for the treatment of insomnia (marketed under the trade name Silenor). Doxepin (as Sinequan) has been used for more than 40 years for the treatment of depression, but hypnotic effects at low doses (3–6 mg) were also reported. Doxepin reduces wake after sleep onset (WASO) and prolongs sleep time. Several other selective H_1 blockers and H_1 reverse agonists are also under development for hypnotic uses.

Melatonin

Melatonin is a neurohormone produced by the pineal gland during the dark phase of the day–night cycle. In animals, melatonin has been implicated in the circadian regulation of sleep and in the seasonal control of reproduction. Studies suggest that melatonin administration may have some therapeutic effects in various disturbances of circadian rhythmicity, such as jet lag (Arendt et al. 1987), shift work (Folkard et al. 1993), non-24-hour sleep–wake cycle in blind subjects (Arendt et al. 1988), and delayed–sleep phase insomnia (Dahlitz et al. 1991), an effect associated with few side effects (e.g., headaches or nausea). High doses of melatonin (3–100 mg), which increase serum melatonin levels far beyond the normal nocturnal range, have been suggested to produce hypnotic effects in humans. Lower and more physiological doses of melatonin (e.g., 0.3 mg) also might be active, but the data available to date are less convincing.

In humans, the production of melatonin during the dark period declines with age; this effect parallels declines in sleep quantity and quality (Van Coevorden et al. 1991), especially in elderly persons with insomnia (Haimov et al. 1994; Mishima et al. 2001). These results seemingly suggest that deficiency in nocturnal melatonin secretion might contribute to disrupted sleep in the elderly; thus, in this population, insomnia is a particularly attractive indication for melatonin. Indeed, some studies reported favorable effects with supplementary administration of melatonin in elderly persons with sleep maintenance disturbances (Garfinkel et al. 1995; Haimov et al. 1995). However, several recent studies reported contradictory findings indicating no significant relation between physiological melatonin secretion levels and sleep maintenance parameters (Hughes et al. 1998; Lushington et al. 1998; Youngstedt et al. 1998; Zeitzer et al. 1999) as well as no significant therapeutic effect of melatonin replacement on sleep maintenance in elderly persons with insomnia (Hughes et al. 1998).

One of the difficulties in establishing therapeutic efficacy of melatonin is its short half-life (20–30 minutes). Bedtime melatonin administration reduces sleep latency but has few objective effects on sleep architecture. It is also unclear whether the hypnotic effect of a physiological or pharmacological dose is a direct effect on sleep, an indirect effect on circadian timing that subsequently gates the release of sleep, or both. Finally, very few double-blind, placebo-controlled studies have been done, and most current reports are confounded by strong placebo effects in the context of a melatonin fad. Melatonin might be an effective hypnotic in some indications, but better controlled studies are needed to establish efficacy in specific indications. The purity of the products sold in health food stores is also a problem, and the long-term effects of melatonin administration in humans are unknown.

There are at least three subtypes of melatonin receptors with high (MT_1) and low (MT_2 and MT_3) affinities for this ligand (Dubocovich 1995; Dubocovich et al. 2003; Morgan et a 1994). MT_1 receptors are high-affinity receptors that fall into the G protein–coupled receptor superfamily; binding of melatonin to these receptors results in inhibition of adenylate cyclase activity in target cells (Ebisawa et al. 1994). The MT_1 receptor is further divided into two subclasses, MT_{1a} and MT_{1b} (Reppert et al. 1994, 1995). The localization of the MT_{1a} receptor in the SCN and median eminence in humans and rodents suggests that this receptor is essential for circadian regulation and reproduction, whereas the MT_{1b} receptor is localized mainly in the retina. The MT_3 receptor appears almost exclusively in the gut. MT_2 receptors are coupled to phosphoinositol hydrolysis. Activation of MT_3 receptors inhibits leukotriene B_4–induced leukocyte adhesion and decreases intraocular pressure (Dubocovich et al. 2003). The functional importance of MT_{1b}, MT_2, and MT_3 remains unclear.

Ramelteon, a melatonin receptor agonist with both high affinity for melatonin MT_1 and MT_2 receptors and selectivity over the MT_3 receptor, and with a longer half-life than melatonin, has recently been approved by the FDA for long-term treatment of insomnia, particularly for delayed sleep onset. Ramelteon does not show any appreciable binding t $GABA_A$ receptors, which are associated with anxiolytic, myorelaxant, and amnesic effects. Ramelteon has not been demonstrated to produce dependence and has shown no potential for abuse, and the withdrawal and rebound insomnia typically seen with other GABA modulators are not present.

Animal studies demonstrated that sleep-enhancing effects of ramelteon are not associated with reduction in REM sleep (Miyamoto et al. 2004). It is currently the only nonscheduled prescription drug for the treatment of insomnia available in the United States. Ramelteon has no appreciable affinity for receptors that bind neuropeptides, cytokines, serotonin, dopamine, norepinephrine, acetylcholine, and opiates. It also does not interfere with the activity of a number of selected enzymes in a standard panel. The activity of ramelteon at the MT_1 and MT_2 receptors, especially on the SCN, is believed to contribute to its sleep-promoting properties, as these receptors, acted upon by endogenous melatonin, are thought to be involved in the maintenance of the circadian rhythm underlying the normal sleep–wake cycle.

The biological action of melatonin is similar to that of ramelteon. No published studies have indicated whether ramelteon is more or less safe or effective than melatonin, a much less expensive drug widely available in the United States without a prescription. Several other MT_1/MT_2 receptor agonists are under development.

A prolonged-release melatonin (marketed under the trade name Circadin) was approved by the European Commission in June 2007 as monotherapy for short-term treatment of primary insomnia characterized by poor-quality sleep in patients 55 years and older (Lemoine et al. 2007).

Thalidomide

Thalidomide is a unique hypnotic compound that deserves special mention. The compound was first introduced as a sleep-inducing agent in the 1950s but was rapidly withdraw after reports of secondary fetal malformations. In the 1960s, thalidomide was found to be surprisingly effective in the treatment of severe granulomatous skin complications associated with leprosy (e.g., erythema nodosum). Since then, thalidomide has been reintroduced to treat various conditions that involve pathological immune reactions (e.g., graft-versus-host disease, lupus) and pharyngeal ulcerations in patients with AIDS (see Kaplan 1994). In patients with leprosy and AIDS, thalidomide inhibited the production of tumor necrosis factor–α (TNF-α). The efficacy of thalidomide in multiple myeloma was reported in the medical literature in 1999 (Desikan et al. 1999). In 2006, the FDA granted accelerated approval for thalidomide in combination with dexamethasone for the treatment of newly diagnosed multiple myeloma.

Together with GHB and ramelteon, thalidomide increases REM sleep and SWS (Frederickson et al. 1977; Kaitin 1985) (benzodiazepines and barbiturates decrease REM sleep and deep SWS). Thalidomide does not bind to or enzymatically modify any neurotransmitter systems known to be involved in the regulation of sleep (e.g., histamine, serotonin, benzodiazepine, excitatory amino acids, and GABA) (Kanbayashi et al. 1996). Thalidomide thus may affect sleep through neuroimmune interactions in the brain, because TNF-α and other cytokines secreted by microglia in the brain have been reported to be endogenous sleep-modulating substances (Krueger et al. 1995). Thalidomide inhibits TNF-α gen expression in the brain and in peripheral tissue such as spleen (Nishino et al. 2005). When administered to TNF-α knockout mice, thalidomide enhanced SWS in these animals, but REM enhancement was not observed (Nishino et al. 2005), suggesting that REM enhancement but not SWS enhancement of thalidomide is dependent on inhibition of TNF-α. Thalidomide analogs with hypnotic effects and/or immunomodulatory effects without any teratogenic effects in animals are available for experimental use but have never been developed for clinical use. Thalidomide thus remains a unique and powerful pharmacological tool in studying the regulation of normal and abnormal sleep, which could lead to the development of new hypnotic agents.

GENERAL CONSIDERATIONS IN THE PHARMACOLOGICAL TREATMENT OF INSOMNIA

Insomnia is a subjective complaint of insufficient, inadequate, or nonrestorative sleep (Buysse and Reynolds 1990; see also Chapter 60, "Treatment of Insomnia"). Disturbances in daytime functioning, such as fatigue, mood disturbances, and impaired performance, result from inadequate sleep. Insomnia is a common symptom. In 1983, a survey indicated that 35% of the general population reported having trouble sleeping in the past year, and 17% considered their problem serious (Mellinger et al. 1985). In the same survey, 7.1% of the population had used a hypnotic in the past year (Mellinger et al. 1985).

Insomnia is a symptom that must be explored clinically before treatment is initiated. Sleep disturbances often indicate a larger psychiatric problem, such as depression. As mentioned above, a complaint of insomnia is also common with old age, especially in an institutional setting. In other cases, environmental factors (e.g., noise) and associated sleep disorders (periodic leg movements, sleep apneas, parasomnias) may be involved.

A useful initial approach to the patient with insomnia is to consider the duration of the complaint. Insomnia can occur as a transient (1–2 days), short-term (more than a few days to a few months), or chronic disturbance (several months or even years). The duration of insomnia not only suggests its cause (Table 42–3) but also provides some guidance on how to use hypnotics.

Transient insomnias are typically caused by an environmental acute stressor, jet lag, or shift work. In this indication, pharmacotherapy with benzodiazepine hypnotics or other hypnotics has no risks because dependence on the treatment is unlikely to develop when the therapy lasts less than a week to 10 days.

Short-term (a few days to a few months) insomnias are particularly important to recognize because they may evolve into chronic psychophysiological insomnia if untreated or inadequately treated. Typically, patients develop insomnia during a stressful period of their lives (e.g., work or personal difficulties). The condition frequently worsens if untreated, and the patient worries excessively about his or her sleep, which evolves into a behaviorally learned, chronic insomnia that does not resolve once the stressful period is over. In this indication, the daily use of benzodiazepine hypnotics is also dangerous because it may lead to tolerance and dependence. Reassurance regarding the favorable resolution of the stressful event is important, and the patient should be instructed to use hypnotic medications intermittently (e.g., every few days, as needed) to avoid the development of tolerance. An education in sleep hygiene (not taking naps even when very tired, having regular wake-up times, avoiding caffeine and alcohol) is also important to reduce the possibility of evolution into a chronic problem.

Chronic insomnia should first be evaluated with a sleep log of a 2-week period. Most commonly, some degree of sleep-state misperception is present, and patients with insomnia greatly exaggerate the complaint (i.e., they sleep more than they claim and take less time to fall asleep than they report). In most cases, insomnia has developed as a result of psychological factors and negative conditioning, as mentioned above. In rare cases, insomnia began in childhood and has persisted into adulthood (idiopathic insomnia). In chronic insomnia, improved sleep hygiene and various behavioral techniques that aim to reduce negative conditioning (stimulus control therapy), sleep restriction, and phototherapy are often helpful on a long-term basis, but these methods are successful only if the patient is motivated and if specialized clinical supervision is available. Drug use is most appropriate in patients whose sleep disturbance is clearly causing some daytime dysfunction. If the clinician decides to use pharmacotherapy, it is always helpful to start with the lowest dose of hypnotic possible (hypnotic medications are frequently overdosed) to reduce the risk of tolerance and dependence and to try to avoid daily use.

Insomnia also can be classified on the basis of individual clinical features—that is, as sleep initiation, sleep maintenance, or termination (early-morning awakening). In this context, the most important pharmacological properties to consider when selecting a hypnotic for treatment are how quickly it acts and how long the effects last (see Table 42–2 for commonly used compounds). The rate of absorption is the most critical factor determining onset of action. T_{max} (time required to reach the maximal plasma concentration) is the pharmacological parameter that best predicts onset of action. After absorption, hypnotics are distributed to various organs; distribution and drug elimination influence the duration of action. The elimination half-life (see Table 42–2) usually provides a good first estimate of the duration of action for drugs that have comparable absorption and distribution profiles. Hypnotics with long duration of action are helpful for patients who have difficulty both initiating and maintaining sleep. One advantage of these long-acting compounds is that rebound insomnia is often delayed and milder if the drug has to be withdrawn (see Figure 42–6). Patients who have difficulty initiating sleep might prefer short-acting compounds; however, for these compounds, it may be necessary, paradoxically, to switch to longer-acting hypnotics before withdrawal of all hypnotic treatment.

The importance of determining whether insomnia is the symptom of an underlying neuropsychiatric condition must be emphasized (see Table 42–3). For depression, trazodone (25–50 mg), amitriptyline (10 mg), trimipramine (25–50 mg), or doxepin (25–50 mg) can be used as a hypnotic or in combination with another hypnotic. Most persons with schizophrenia also have persistent insomnia (initiation and maintenance of sleep), and phenothiazines, such as chlorpromazine, thioridazine, and levomepromazine, are effective therapies. When psychotic symptoms are associated with insomnia, butyrophenones, such as haloperidol, also can be used. For insomnia associated with anxiety disorders, hypnotics supplemented with anxiolytics can be used, and this treatment may prevent rebound insomnia and its related anxiety.

Sleep disturbances are very frequent complaints in old age, and treatment must be initiated carefully in this population (see Chapter 65, "Treatment During Late Life"). About 12% of the United States population is older than 60 years, and this segment of the population receives 35%–40% of all sedative-hypnotic prescriptions (Gottlieb 1990).

Before starting pharmacological therapy, all possible causes of insomnia should be examined (i.e., psychophysiological; associated with drugs and alcohol; due to disturbance of the sleep–wake cycle; associated with periodic leg movements, sleep apnea, or other physical or psychiatric conditions). Before selecting a specific hypnotic, the clinician should consider its pharmacological properties and side-effect profile, the patient's medical health and medical history, and the patient's history of sedative-hypnotic use. The special case of melatonin has been discussed earlier in this chapter. Hypnotics or their active metabolites often accumulate during chronic use in elderly patients, and this accumulation

may cause cognition problems, disorientation, confusion, and, occasionally, falls. Hypnotics with short or intermediate half-lives are thus recommended, and the lowest dose possible should be used. Compounds with a short half-life, such as triazolam or zolpidem, may be effective for problems with sleep initiation and sleep fragmentation. Zolpidem has little muscle relaxant effect and may be preferable. Compounds with an intermediate hypnotic profile, such as estazolam and temazepam, are also reported to be effective in elderly patients. Hypnotics with intermediate half-lives may alter daytime performance and memory to a lesser extent and are not as likely to induce rebound insomnia after withdrawal as are regular hypnotics.

CONCLUSION

The mechanism of action of most currently available hypnotics (benzodiazepines, barbiturates, alcohol, and recent nonbenzodiazepine hypnotics) involves a modulatory effect o GABAergic activity. These compounds stimulate GABAergic transmission by acting on the $GABA_A$–benzodiazepine–Cl^- macromolecular complex, known to contain multiple modulatory binding sites and many receptor subtypes. This recently discovered molecular diversity within the macromolecular complex suggests that new GABAergic hypnotic compounds with subtype selectivity may have better side-effect profiles.

Other non-GABAergic hypnotics, including mostly sedative antidepressants, antihistamines, and melatonin and melatonin receptor agonists, are viable strategies in the treatment of insomnia, especially because these hypnotics may lack some of the hampering side effects often seen with classical GABAergic hypnotics, such as abuse potential and amnesic effects. Their prescription, as with the prescription of other regular benzodiazepine-like hypnotic compounds, should be guided by the knowledge that insomnia is a heterogeneous condition that should be explored clinically before any pharmacological treatment is initiated.

Chapter 43. Psychostimulants and Wakefulness-Promoting Agents

PSYCHOSTIMULANTS AND WAKEFULNESS-PROMOTING AGENTS: INTRODUCTION

Amphetamine, first discovered in 1887, and the subsequently developed stimulants have been used in clinical psychiatry with varying results. Beyond their use for attention-deficit/hyperactivity disorder (ADHD), they have been used for symptomatic relief based on their effects on mood and hedonic drive. Research into the use of stimulants as adjunctive agents in the treatment of specific symptoms and syndromes has been increasing. Evaluation of new medications, such as modafinil and armodafinil, which are classified as wakefulness-promoting agents, has further heightened interest in a possible therapeutic role for such agents in treatment of neurobehavioral disorders. Various common adjunctive psychotherapeutic uses for stimulants, such as depression, have not been well researched, while other indications, such as narcolepsy, are backed by considerable clinical data. Nonetheless, much more data are needed on the safety and efficacy of traditional psychostimulants as well as the newer agents in the treatment of psychiatric disorders. In this chapter, we review the pharmacology of these medications and their indications (Tables 43–1 and 43–2).

AMPHETAMINES

Structure–Activity Relations

Structurally, amphetamine is phenylisopropylamine. Ultimate pharmacological action is determined by alterations to any of the three basic parts of the amphetamine molecule.

Amine Changes

In terms of affecting clinical utility, substitution at the amine group is the most common alteration. Methamphetamine (both L and D isomers), which is characterized by an additional methyl group attached to the amine, making it a secondary substituted amine, is more potent than amphetamine. Likewise, *N*-hydroxyamphetamine, a minor metabolite of amphetamine, is more potent than unsubstituted amphetamine. Usefully, one may think of the amine group as enhancing stimulant-like properties. Nevertheless, it may have the reverse effect on the hallucinogenic properties of entactogens, as described later in this section.

Isopropyl Changes

An intact isopropyl side chain appears to be needed in order to maintain the potency of amphetamine. For example, changing the propyl to an ethyl chain creates phenylethylamine, an endogenous neuroamine (and metabolite of the monoamine oxidase inhibitor [MAOI] phenelzine), which has mood- and energy-enhancing properties but less potency and a much shorter half-life than amphetamine (Janssen et al. 1999).

Aromatic Changes

Substitutions on the phenyl group are associated with a decrease in amphetamine-like properties. Interestingly, reduction of the phenyl to a cyclohexyl ring reduces the potency, but not the efficacy, of amphetamine properties. Unlike changes at the amine or isopropyl level, additions to the aromatic ring substantially alter the effects of the compound. The most common changes at the aromatic ring are of the methoxy type and are associated with hallucinogenic properties. For example, adding a para-methoxy group (paramethoxyamphetamine) creates a hallucinogen. The street drug referred to as "Ecstasy" (3,4-methylenedioxy-*N*-methylamphetamine, or MDMA) is built on a methamphetamine backbone, with a dimethoxy ring extending from the aromatic group. If this hallucinogen is instead designed without the methyl group on the terminal amine, making it a primary amine (i.e., 3,4-methylenedioxy-*N*-amphetamine or MDA), as is the case with the street drug referred to as "Love," the hallucinogenic potency and duration are further increased. Consequently, substitution at the terminal amine clearly increases amphetamine-like properties. However, the agents MDMA, MDA, and the ethylated form (3,4-methylenedioxy-*N*-ethylamphetamine, or MDE) are referred to collectively as *entactogens* to distinguish them from simple stimulants or hallucinogens.

Stereospecificity

Recently, there has been renewed interest in drugs that are pure stereoisomers, as opposed to racemic mixtures, especially with the recent release of dexmethylphenidate (the dextro isomer of methylphenidate) and escitalopram (the levo isomer of citalopram). In the case of amino acids and sugars, only one stereoisomer (the L amino acid and the D sugar, respectively) is used by the body. It is erroneously assumed that the comparable situation exists for medications (i.e., that only one isomer is biologically active). This is an oversimplification, however. For example, with respect to amphetamine isomers, it is true that the dextro form (i.e., dextro isomer, or dextroamphetamine) is almost twice as potent as the levo form (i.e., levo isomer, or levoamphetamine) in promoting wakefulness, but they are of equal potency in reducing cataplexy and rapid eye movement (REM) sleep (Nishino and Mignot 1997). Similarly, whereas the dextro isomer has a more potent effect on dopamine efflux than does the levo isomer form, they are equally potent in promoting norepinephrine efflux (Kanbayashi et al. 2000). The effect on dopamine reuptake is, like the effect on efflux, stereospecific; inhibition in rat brain, striatum, and hypothalamus has been found to be markedly different between the two isomers (Ferris and Tang 1979). This is not surprising, given that dopamine efflux and reuptake may be mediated by the same transport mechanism (see subsection "Mechanism of Action" later in this section). There does not appear to be any difference in the enantiomeric specificity of amphetamine to monoamine oxidase A or B (Robinson 1985).

Amphetamine stereospecificity is not generalizable across other amphetamine compounds. For example, both individual isomers of MDMA, as well as the racemic mixture, have the same potency in reinforcement (Meyer et al. 2002). MDE, by contrast, appears to have an *(R)*-mediated neurotoxicity and an *(S)*-mediated entactogenic specificity. The *(S)* isomer induces more euphoria, while the *(R)* isomer induces more depression (Spitzer et al. 2001). Because many of these studies have been done in animals, it remains to be seen if the stereospecificity of these compounds will be detectable or important in humans.

The clinical utility of stereospecificity is unclear. Urine levels of the levo isomer have been used to measure compliance in amphetamine-addicted patients prescribed dextroamphetamine for maintenance or detoxification; the logic is that the more levo isomer present in urine, the less compliance (George and Braithwaite 2000).

Perhaps the most clinically useful difference between amphetamine isomers involves their differential effects on reinforcement. Studies in rats have shown that the dextro isomer is four times more potent than the levo isomer in promoting lever pressing for intracranial stimulation (Hunt and Atrens 1992). However, that pure dextroamphetamine is better for the treatment of ADHD than, for example, the mixed salts of dextroamphetamine/amphetamine is neither obvious nor conclusively shown. In

addition, the overall greater potency of the dextro form to central actions suggests that this form may have a higher potential for abuse.

Methamphetamine, differing from amphetamine by the presence of a methyl group, is more rapidly absorbed into the central nervous system (CNS) and possesses a longer half-life (approximately 20 hours). The increased toxicity of methamphetamine is believed to be due to a combination of its rapid absorption into the CNS, its potency in causing dopamine and glutamate release, and through a mechanism similar to neuronal apoptosis. The toxicity of methamphetamine is mediated via the mitochondria by the generation of free radicals (Choi et al. 2002)—a process inhibited by both glutathione and L-carnitine (Virmani et al. 2002) (see subsection "Side Effects and Toxicology" later in this section).

Pharmacological Profile

Amphetamines are noncatecholamine, sympathomimetic amines with CNS stimulant activity that causes catecholamine efflux and inhibits the reuptake of these neurotransmitters (see subsection "Mechanism of Action" later in this section).

Pharmacokinetics and Disposition

Amphetamines are highly lipid soluble and achieve peak levels in approximately 2 hours. Because of this lipid solubility, amphetamines have rapid distribution into tissues and transit across the blood–brain barrier. The protein binding is highly variable, but the average volume of distribution, or V_d, is 5 L/kg.

Because amphetamine is a weak base, much of its elimination can be altered. In general, the half-life is approximately 16–30 hours. If the urine is acidified, excretion can be increased to approximately 60% of the unaltered amphetamine in 48 hours. Alkalinizing the urine, however, can drive the elimination almost totally through a metabolic pathway (deamination).

On average, 30% of amphetamine is excreted unchanged, although the dextro isomer is more rapidly excreted. Another 20% (or substantially more, depending on the pH of the urine) of amphetamine is deaminated to phenylacetone and, to a trivial extent, parahydroxyamphetamine. Phenylacetone is in turn oxidized to benzoic acid and excreted as hippuric acid. A small but likely clinically insignificant metabolism (hydroxylation) occurs through the cytochrome P450 (CYP) 2D6 isoenzyme (see subsection "Drug–Drug Interactions" later in this section).

Mechanism of Action

The classic mechanism of action of amphetamines involves rapid diffusion directly into neuron terminals; through dopamine and norepinephrine transporters, amphetamine enters vesicles, causing release of dopamine and norepinephrine. The release of these neurotransmitters into the synapse mediates some of the psychological and motoric effects of amphetamine, including euphoria, increased energy, and locomotor activation.

However, the actual mechanism of action of amphetamine appears to be more complex than simply promoting dopamine or norepinephrine efflux. This is most notably observed with respect to dopamine. Release of dopamine is a two-step process: 1) release from the vesicles into the presynaptic terminal and then 2) release from the presynaptic terminal into the synaptic cleft. Although amphetamine rapidly caused the release of dopamine from the vesicles into the presynaptic terminal, in knockout mice lacking an intact dopamine transporter (DAT), dopamine was not released into the synaptic cleft, thus showing that the role of the DAT is the rate-limiting step in the effects of amphetamine (Jones et al. 1998). This finding led to the further discovery that the DAT functions in a bidirectional manner; its transport of amphetamine from extracellular space into the presynaptic terminal both diminishes the amount of dopamine that is taken back into the presynaptic terminal and

catalyzes a reaction promoting the outward transport of dopamine from the presynaptic membrane to the synaptic cleft (Jones et al. 1999).

The dopaminergic effects of amphetamines are opposite those found for the norepinephrine transporter (NET). Knockout mice lacking the NET were supersensitive to the locomotor stimulation of amphetamine. It appears that in the absence of norepinephrine transport, there is no feedback control on amphetamine-induced dopaminergic function (Xu et al. 2000). The primacy of dopamine in the effects of amphetamine is similarly revealed by the observation that amphetamine decreases γ-aminobutyric acid (GABA)–ergic transmission in the striatum through stimulation of dopamine$_2$ (D_2) receptors (Centonze et al. 2002). This likely represents an important, albeit not yet quantified, contribution to the psychostimulant effects of amphetamines.

One hypothesis concerning how amphetamines paradoxically suppress or reduce hyperactivity in certain patient populations has been dispelled. It was believed that at certain therapeutic doses (which are in actuality low doses compared with those that produce locomotor activation and stereotypy), amphetamines bind to presynaptic autoreceptors and prevent neurotransmission. This belief has not been supported; results from a 2001 study showed that at doses as low as 0.2 mg/kg (even lower than traditional therapeutic doses), amphetamine still had low affinity for the autoreceptor and was much more potent at the postsynaptic site (Ruskin et al. 2001). It appears that the mechanism of putative paradoxical effects of amphetamine administered at low doses remains to be identified.

With respect to the anorectic effects of amphetamines, the role of hypothalamic neuropeptide Y (NPY), a potent stimulant of appetite, is being considered as a possible mechanism. In ordinary circumstances, the anorectic effects of amphetamines are seen on the first day, but tolerance to this appetite suppressant effect quickly develops. It has been reported that the level of hypothalamic NPY markedly decreases on the first day of amphetamine administration but then quickly returns to normal. This tolerance was abolished with a daily dose of NPY antisense treatment (which effectively blocks the expression of the NPY gene) (Kuo et al. 2001).

Precisely how amphetamines enhance waking cognitive functions is not known. A repeated finding is increased activity in the brain, whether measured as regional cerebral blood flow in positron emission tomography (PET) scans (Mattay et al. 1996) or as activated voxels in functional magnetic resonance imaging (Uftring et al. 2001). In a given task, the brain regions that are active during amphetamine administration are those that are also active during placebo administration; in other words, amphetamine did not activate new brain areas to produce its effect (Uftring et al. 2001). A more controversial but quite impressive discovery in the PET study by Mattay et al. (1996) was that whereas amphetamine increased cerebral blood flow in task-specific regions, it decreased blood flow in those regions not needed in the task, forming the basis for the hypothesis that amphetamine acts in a "neural network–specific" manner. Methylphenidate showed similar effects in a study of 11 children with attention-deficit disorder. The drug increased perfusion in the mesencephalon but decreased it in motor and sensory areas (Lou et al. 1984). Caffeine, by contrast, does not appear to have this region-specific effect but instead affects cerebral blood flow more globally (Cameron et al. 1990).

Side Effects and Toxicology

The side effects of amphetamines are predictable relative to their sympathomimetic pharmacology. The most common effects are nervousness, agitation, and decreased sleep. Serious adverse consequences have been observed with amphetamines, including arrhythmias, hyperpyrexia, rhabdomyolysis, and convulsions. Death, although uncommon, generally occurs only after the manifestation of one of these symptoms. Hallucinosis and psychosis are frequent complications of injected or inhaled amphetamines but uncommon with oral intoxication.

Methamphetamine is more frequently associated with complications; because of its higher toxicity, it

is not clear whether severe complications are dose dependent. For example, in a retrospective study of methamphetamine-related deaths in a large city, methamphetamine use was significantly associated with a higher risk of coronary artery disease, as well as a higher rate of subarachnoid hemorrhage, although it was of course impossible to determine whether the subjects were first-time users or chronic abusers (Karch et al. 1999). Of particular note in this study, however, was that blood levels of methamphetamine did not differ between the group in which methamphetamine was judged to be the cause of death and the group in which methamphetamine was detected but judged not to be related to the cause of death, suggesting that these toxicities are not necessarily dose dependent. Similarly, in one 5-year study, methamphetamine accounted for 43% of rhabdomyolysis cases in an emergency department setting. Methamphetamine rhabdomyolysis was associated with substantially higher creatine phosphokinase (CPK) values (mean = 12,439 U/L) (Richards et al. 1999). Similarly, hyperthermia is a common cause of death and may in fact be the cause of rhabdomyolysis (Callaway and Clark 1994). Thus, in contrast to the relative safety of oral amphetamines, methamphetamine carries greater risks.

Methamphetamine is more neurotoxic than amphetamine; it can cause destruction of dopaminergic neurons in the basal ganglia and, thus, is widely suspected to increase the likelihood of future parkinsonism (Guilarte 2001). Although it is commonly believed that MDMA ("Ecstasy") is primarily toxic to serotonergic neurons (Sprague et al. 1998), evidence shows that it is also toxic to dopaminergic neurons (Ricaurte et al. 2002).

Methamphetamine appears to increase free radicals and causes mitochondrial damage and decreased adenosine triphosphate (ATP) synthesis. In dopaminergic neurons, the neurotoxicity is mediated by formation of peroxynitrite, which can be reduced by antioxidants or L-carnitine (Virmani et al. 2002). L-Carnitine is needed to transport long-chain fatty acids into the mitochondria for fatty acid oxidation, preventing the generation of free radicals and peroxynitrite. MDMA appears also to decrease glutathione and vitamin E (in brain), and mice deficient in vitamin E were found to have greater susceptibility to both MDMA neurotoxicity and hepatic necrosis, further supporting a free radical mechanism for toxicity (Johnson et al. 2002).

Seizures are fairly common in amphetamine abuse scenarios, especially with the more potent methamphetamine and hallucinogenic analogs. Some differences are seen in the phenotype of seizures from different stimulants. Methamphetamine produced the longest seizure, and cocaine produced the shortest; however, although phenytoin effectively prevented cocaine seizures, it had no effect on methamphetamine seizures, which could be prevented only by diazepam and valproate. MDMA was unique in that it produced a secondary clonic phase after the initial seizure (Hanson et al. 1999). It should be noted that the most common complication of MDMA is seizures (Zagnoni and Albano 2002); thus, MDMA always should be suspected in new-onset seizures in patients of the appropriate demographic.

Stimulant psychosis—often referred to as *paranoid psychosis*—is also common in amphetamine abuse scenarios because of the overwhelming presentation of the eponymous symptom. Visual hallucinations are also disproportionately common with amphetamine psychosis; in contrast, disorientation and thought disorder, which are more common in schizophrenia, are rarely seen (Angrist et al. 1974). Psychosis is often seen together with stereotypy. In humans, stereotypy can take many forms but usually is expressed as pacing, searching, or examining minute details.

Traditionally, stimulants have been contraindicated in patients with tics because stimulants are believed to worsen tics; the prescribing information notes that dextroamphetamine exacerbates motor and phonic tics and Tourette's syndrome (GlaxoSmithKline 2006). This relation is not consistently found (Law and Schachar 1999) and is discussed in further detail below.

The U.S. Food and Drug Administration (FDA) has added a black box warning to all stimulant

medications, describing the risks of heart-related problems, especially sudden death in those with prior cardiac disease; stroke; and increased blood pressure and heart rate. Additionally, the warning describes the risk of new mental problems, especially bipolar disorder, hostility, or psychosis.

Drug–Drug Interactions

A comprehensive review found that drug interactions with amphetamine were mostly pharmacodynamic in nature (Markowitz and Patrick 2001); however, because a small portion of amphetamine's metabolism occurs via CYP2D6, those drugs that inhibit 2D6 metabolism can, theoretically, have the effect of increasing the plasma level of amphetamines. This is generally not a significant effect with therapeutic doses of amphetamines; however, more severe reactions are possible with the inhibition of CYP2D6 metabolism of MDMA (Ramamoorthy et al. 2002) and paramethoxyamphetamine (Kraner et al. 2001), which are more toxic compounds. Only two reported cases of serotonin syndrome have been associated with amphetamine and venlafaxine or citalopram use (Prior et al. 2002).

LISDEXAMFETAMINE

Lisdexamfetamine dimesylate, a prodrug that on absorption is metabolized to dextroamphetamine and L-lysine, was approved in 2007 for the treatment of ADHD. Food does not affect absorption of lisdexamfetamine; however, as with all amphetamines, acidification of the urine results in more rapid clearance.

Two small studies in children found good efficacy and tolerability for lisdexamfetamine in the treatment of ADHD. A 4-week randomized, double-blind, forced-dose, parallel-group study compared lisdexamfetamine 30, 50, or 70 mg with placebo in children (ages 6–12 years) with ADHD (Biederman et al. 2007b). Efficacy, as measured by the ADHD Rating Scale–Version IV (ADHD-RS-IV), the Conners Parent Rating Scale (CPR), and the Clinical Global Impression of Improvement scale, was statistically superior to placebo for all doses tested. A randomized, double-blind, placebo-controlled crossover study compared lisdexamfetamine with placebo and mixed amphetamine salts extended-release (Adderall XR) in 52 children (ages 6–12 years) with ADHD in an analog classroom setting (Biederman et al. 2007a). The study found comparable efficacy and safety for the active medications and superiority over placebo as measured by CGI and Swanson, Kotkin, Agler, M-Flynn, and Pelham (SKAMP)–Deportment scores.

In 420 adults, a 4-week forced-dose study (30, 50, and 70 mg) found lisdexamfetamine to have significantly greater efficacy over placebo as measured by ADHD-RS scores. Human liability studies have also found lower abuse-related drug-liking scores compared with immediate-release D-amphetamine at equivalent doses (Najib 2009).

METHYLPHENIDATE

Structure–Activity Relations

Although methylphenidate has two chiral centers, only one contributes to its clinical effect. The D- and L-threo enantiomers are in a racemic mixture, although a single-isomer form of methylphenidate, dexmethylphenidate [*(R,R)*-(+)], is currently being marketed under the brand name Focalin. There are some differences in the pharmacological parameters of the two isomers, as described in the following subsection.

Pharmacokinetics and Disposition

Methylphenidate is almost totally absorbed on oral administration (as is the single isomer dexmethylphenidate), although it is absorbed at a faster rate in the presence of food (Chan et al. 1983). Methylphenidate has low protein binding (15%) and is fairly short acting; the effects last approximately 4 hours, with a half-life of 3 hours. The primary means of clearance is through the

urine, in which 90% is excreted.

There is a substantial albeit likely clinically insignificant difference in the metabolism of the two isomers of methylphenidate. If the racemic mixture is given intravenously, there is no difference in urine D- or L-methylphenidate levels, and there is no difference in the metabolite isomer levels, D- and L-ritalinic acid. However, if a racemic mixture is given orally, urine D-methylphenidate levels are 10 times that of L-methylphenidate levels, whereas levels of L-ritalinic acid are almost three times greater than those of D-ritalinic acid (Srinivas et al. 1992, 1993). This difference can be explained by the fact that L-methylphenidate, but not D-methylphenidate, undergoes significant first-pass metabolism (by de-esterification) to L-ritalinic acid.

Mechanism of Action

Although it is both a norepinephrine and a dopamine reuptake inhibitor, methylphenidate appears to exert its effects primarily through its action on dopamine neurobiology. It blocks the DAT and increases extracellular dopamine. The amount of extracellular dopamine increase varies greatly among individuals depending on the extent of both DAT blockade and baseline dopamine release. It is hypothesized, therefore, that methylphenidate will be more potent in someone with a high baseline level of dopamine release (Volkow et al. 2001).

Because of studies showing that the dextro isomer is a more potent locomotor activator than the levo isomer and that there is no difference between the levo form and placebo in improving attention (Challman and Lipsky 2000), it is at times proposed that the levo form is thus entirely inactive in the human body. This is not wholly accurate, however, because there are differences in isomer binding among brain regions. For example, the dextro form binds stereoselectively in the striatum and basal ganglia, whereas the levo form binds nonspecifically throughout the brain (Challman and Lipsky 2000).

Side Effects and Toxicology

The common side effects of methylphenidate are similar to those of amphetamine and include nervousness, insomnia, and anorexia, as well as dose-related systemic effects such as increased heart rate and blood pressure. Overdose may lead to seizures, dysrhythmias, or hyperthermia (Klein-Schwartz 2002). At therapeutic doses, discontinuation symptoms tend to be slight, but with chronic abuse, symptoms similar to those in amphetamine withdrawal, including lethargy, depression, and paranoia, can occur (Klein-Schwartz 2002).

Although worry over the possibility that methylphenidate worsens tics is common, controlled trials indicate that this concern may be unfounded (Castellanos et al. 1997; Law and Schachar 1999). At least one such controlled study found that in children with comorbid tic disorder, tic severity was no worse with methylphenidate than with placebo until approximately 12 weeks, at which point the tic severity actually improved with methylphenidate (Tourette's Syndrome Study Group 2002).

To date, no evidence has shown that methylphenidate is carcinogenic. Surprisingly, it has been observed that in both rats and humans, the incidence of certain cancers is lower than expected (Dunnick and Hailey 1995). There are case reports of growth impairment in children, possibly due to an effect on growth hormone secretion (Holtkamp et al. 2002), although numerous studies have not found such an effect on growth (Kramer et al. 2000; Lahat et al. 2000; Toren et al. 1997).

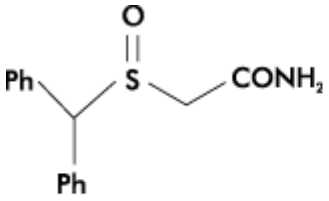
The FDA has added a black box warning to all stimulant medications, describing the risks of heart-related problems, especially sudden death in those with prior cardiac disease; stroke; and increased blood pressure and heart rate. Additionally, the warning describes the risk of new mental problems, especially bipolar disorder, hostility, or psychosis.

Drug–Drug Interactions

Although theoretically a substrate of CYP2D6, methylphenidate was found not to have any significant metabolism in humans via this enzyme (DeVane et al. 2000). This is likely because the vast majority of methylphenidate metabolism occurs at first pass and outside of the liver. The prescribing information (Novartis 2007) does cite methylphenidate's potential ability to inhibit the metabolism of coumadin, some antiepileptics, and tricyclic antidepressants (TCAs), and thus caution should be observed. However, a review found that methylphenidate is relatively safe and has minimal substantial drug–drug interactions, with the exception of concomitant MAOI use (Markowitz and Patrick 2001).

MODAFINIL

Modafinil is the first FDA-designated "wakefulness-promoting agent." Modafinil is approved by the FDA for the treatment of excessive sleepiness associated with narcolepsy, sleep apnea, and residual sleepiness after standard treatment for shift work sleep disorder (Cephalon Inc. 2008). As described below, modafinil does little to prevent or alter sleep when one is trying to do so; however, it appears to permit more stable wakefulness (i.e., reduced sleep propensity) when one is attempting to stay awake in the presence of elevated sleep pressure.



Structure–Activity Relations

Modafinil (2-[(diphenylmethyl)sulfinyl]acetamide) exists in racemic form. Both stereoisomers appear to have the same activity in animals.

Pharmacokinetics and Disposition

Modafinil, the primary metabolite of adrafinil, lacks adrafinil's terminal amide hydroxyl group (Figure 43–1). It also lacks many of the side effects found in adrafinil, such as increased liver enzymes, anxiety, and stomach pain. Modafinil is rapidly absorbed but slowly cleared. It has fairly high protein binding (60%) and a V_d of 0.8 L/kg. Its half-life is 11–14 hours.

The metabolism of modafinil is complex. In contrast to excretion of amphetamines, less than 10% of modafinil is excreted unchanged. For reasons not understood, the dextro isomer is cleared three times faster than the levo isomer, and females clear modafinil faster than do males (Wong et al. 1999a). This sex difference was not observed to correspond to differences in efficacy or tolerability. Armodafinil, although named after the *(R)* isomer, is properly levorotatory (i.e., L-*(R)*-modafinil) and is thus the longer-acting isomer.

Up to 60% of modafinil is converted into modafinil acid and modafinil sulfone, both of which are inactive. Metabolism is primarily via CYP3A4/5. It has been reported that modafinil also has in vitro capacity to induce CYP3A4 (Robertson et al. 2000), especially gastrointestinal 3A4. A clinically significant reduction of triazolam has been reported (Robertson et al. 2002).

Mechanism of Action

The precise mechanism by which modafinil exerts its wakefulness-promoting effect in patients with excessive sleepiness due to narcolepsy is not yet known. Human narcolepsy is associated with a loss

of hypocretin cells in the lateral hypothalamus. Modafinil, given its efficacy in narcolepsy, is not surprisingly observed to increase c-fos activity of hypocretin cells, as well as in the tuberomammillary nucleus (which is primarily histaminergic), striatum, and cingulate cortex at higher doses (Scammell et al. 2000). The precise mechanism of action for modafinil's effects on sleepiness in narcolepsy remains to be determined. Additionally, in rats, an increase in histamine release in the anterior hypothalamus is seen (Ishizuka et al. 2003). Interestingly, humans with narcolepsy have decreased levels of histamine in the cerebrospinal fluid; this, along with the c-fos activity in the histaminergic tuberomammillary nucleus, suggests a histaminergic mechanism (Mignot and Nishino 2005). However, modafinil's wakefulness-promoting effects were not decreased in histamine knockout mice (Bonaventure et al. 2007).

It may be easier to describe the pathways by which modafinil does *not* exert its effects. Modafinil only weakly binds to the DAT and causes a smaller release of dopamine compared with other stimulants. Dopaminergic mechanisms that are affected by traditional stimulants, such as amphetamine, are not thought to account for the wakefulness induced by modafinil. However, in DAT knockout mice, modafinil had no wakefulness-promoting effects (Wisor et al. 2001), suggesting that its mechanism of action may involve some feature of dopamine transport that is necessary for its efficacy. Furthermore, all agents that inhibit dopaminergic function and suppress the effects of stimulants in the form of dopamine$_1$ (D_1) blockade, D_2 blockade, and tyrosine hydroxylase blockade were found to have no effect on modafinil (Simon et al. 1995). A recent in vitro study found that modafinil blocked norepinephrine reuptake in the ventrolateral preoptic nucleus—a putative sleep-promoting center (Gallopin et al. 2004; Saper and Scammell 2004). Norepinephrine ordinarily inhibits sleep-promoting neurons in this area, thereby inhibiting sleep; modafinil therefore increases this inhibition of sleep.

Despite modafinil's having no affinity for α receptors, central α_1 blockers such as prazosin have been reported to block modafinil's wakefulness-promoting action (Duteil et al. 1990). It may be the absence of modafinil's effect on catecholamine levels that explains the lack of rebound sedation that commonly occurs after amphetamine usage.

Modafinil appears to increase glutamate and suppress GABA in the posterior hypothalamus (Ferraro et al. 1999) and medial preoptic area (Ferraro et al. 1996) (as well as increasing glutamate in the hippocampus and ventral thalamus [Ferraro et al. 1997]), a finding consistent with promotion of increased wakefulness.

What may be an important aspect of the pharmacology of modafinil is its lack of effect on the neuroendocrine system. A comparison of healthy volunteers who were sleep deprived for 36 hours with those who received modafinil during sleep deprivation found no difference in cortisol, melatonin, or growth hormone levels (Brun et al. 1998). Modafinil has been reported to increase body temperature in healthy adults undergoing sleep deprivation (Bourdon et al. 1994); however, the increase appears slight (0.15–0.2°C) and does not appear to be disproportionately increased (relative to placebo) by exercise even during sustained wakefulness (McLellan et al. 2002).

Side Effects and Toxicology

Modafinil appears to be well tolerated, with the most frequent side effects being headache and nausea. Side effects have been found to increase with doses from 100 to 600 mg, and very high doses (800 mg) have been found to be associated with higher rates of tachycardia and hypertension (Wong et al. 1999b). In Phase III trials, three patients with a history of mitral valve prolapse or left ventricular hypertrophy had transient ischemic changes on electrocardiogram; one patient taking 300 mg/day for almost a month had a 9-second asystole. One patient with chronic sleep deprivation taking 600 mg/day for several days experienced auditory hallucinations and paranoia, which quickly resolved after discontinuation of the modafinil. Overall, only 5% of the patients in Phase III trials discontinued modafinil because of side effects (Cephalon Inc. 2008).

Modafinil appears to be fairly safe in high doses. Reports indicate that 32 patients have safely taken 1,000 mg/day for more than 50 days; one individual safely took 1,200 mg/day for 21 consecutive days. Two patients took 4,000 mg and 4,500 mg, respectively, at once and experienced only transient (<24 hours) agitation, insomnia, and mild elevations in heart rate and blood pressure (Cephalon Inc. 2008). There have been no reports of seizures with modafinil. However, because modafinil has become clinically available only relatively recently, the results of clinical trials on its safety and efficacy are limited relative to those for many other stimulants. It is anticipated that more published data on modafinil will become available in the coming years.

During the recent attempts to have modafinil approved for ADHD, concern arose over the possibility that modafinil may have a risk of Stevens-Johnson syndrome. Three cases of drug-induced rash were reported during clinical trials (U.S. Food and Drug Administration 2007). In the first, a 7-year-old Asian boy who was concomitantly taking amoxicillin for an upper respiratory tract infection developed rash 16 days after starting modafinil, which by day 23 progressed to what was believed to be Stevens-Johnson syndrome. It was not clear whether this rash was due to the modafinil or to the amoxicillin. The second case involved a girl who developed a maculopapular rash that resolved with antihistamines. In the third case, an 8-year-old boy developed fever, blisters on lips, and rash on cheeks 14 days after initiating modafinil therapy. There was insufficient evidence to diagnose the rash, nor was it clear to the panel that the rash was related to modafinil.

The current package insert describes the risk of "serious rash, including Stevens-Johnson syndrome," in adults and children and cautions that modafinil is not indicated for children. The insert cites a rash incidence of 0.8% in pediatric patients, with one case of possible Stevens-Johnson syndrome and one case of multiorgan hypersensitivity reported, and concludes with the statement that although there are no known predictive factors, and that benign rashes do occur, modafinil should be discontinued if rash develops.

Drug–Drug Interactions

As described earlier in this section, modafinil induces CYP3A4/5 and thus conceivably could lower the plasma concentrations of medications with substantial 3A4/5 metabolism. However, it is not clear if this induction is substantial only on the gastrointestinal cytochrome and is thus relevant only for other drugs undergoing significant first-pass metabolism.

Modafinil inhibits CYP2C19 in vitro (Robertson et al. 2000). It is prudent to assume that the effect of modafinil on the cytochrome system is not well characterized and to be vigilant for these potential drug–drug interactions.

ARMODAFINIL

Armodafinil, properly L-*(R)*-modafinil (or (–)-*(R)*-modafinil), is the longer-acting isomer of racemic modafinil. In 2007, it received FDA approval for the same indications as modafinil—specifically, excessive sleepiness associated with narcolepsy; obstructive sleep apnea/hypopnea syndrome (OSAHS) as an adjunct to standard treatment; and shift work sleep disorder (SWSD).

Armodafinil and racemic modafinil give comparable peak plasma concentrations, although the peak for armodafinil occurs later than that for modafinil and is maintained for 6–14 hours postdose (Dinges et al. 2006).

Although no human equivalence studies have been performed, it appears that in rats, 100 mg/kg armodafinil was equally efficacious to 1 mg/kg D-methamphetamine. In keeping with the differential pharmacology and effects, this comparable dose did not affect locomotor activity or body temperature. While there were no differences in rebound sleep parameters such as latency to consolidated sleep, a greater proportion of time was spent in non-REM sleep with D-methamphetamine than armodafinil —which was not different from placebo. Similarly, brief awakenings, another measure of rebound

hypersomnolence, were suppressed with D-methamphetamine but not with armodafinil (Wisor et al. 2006).

Published data on armodafinil are minimal. At the time this chapter was finalized, a MEDLINE search on the term "armodafinil" returned 11 citations, only 6 of which were actual studies. Two 12-week double-blind studies using armodafinil 150 mg as an adjunct to continuous positive airway pressure (CPAP), both in patients who were otherwise stable except for some residual sleepiness (Hirshkowitz et al. 2006) and in patients who were still symptomatic (Roth et al. 2006), found improvements in wakefulness measures. Armodafinil also significantly improved the quality of episodic secondary memory (i.e., the ability to recall unrehearsed information). Whether this effect was due directly to the medication, to improved wakefulness, or to decreased hypoxia (as a function of being more awake) is unclear. However, armodafinil did not adversely affect the CPAP or any other physiological parameters.

A 12-week double-blind study of armodafinil in narcolepsy found improvements similar to those seen with modafinil. These included improved wakefulness (as measured by the Maintenance of Wakefulness Test), improved Clinical Global Impression of Change (CGI-C) scores, and improvement in memory and attention. Armodafinil 150 mg and 250 mg were similarly effective (Harsh et al. 2006).

In SWSD, armodafinil 150 mg/day was tested versus placebo in a 12-week study, showing significant prolongation of time to sleep onset and an improvement in overall clinical condition by CGI-C. Armodafinil had no effect on daytime sleep polysomnography (Roth et al. 2005).

CLINICAL USES OF STIMULANTS AND WAKEFULNESS-PROMOTING AGENTS

Although stimulants have been used for many years in a number of clinical scenarios, double-blind, randomized, controlled trials examining their safety, efficacy, and effectiveness in neurobehavioral disorders other than ADHD are relatively rare. Most of the support for their use comes from open-label studies and case series. Randomized trials on modafinil for neurobehavioral disorders with symptoms of sleepiness and fatigue are beginning to be published.

Attention-Deficit/Hyperactivity Disorder

Several double-blind, placebo-controlled studies have shown the efficacy of stimulants for ADHD, and their use is well investigated in both adults and children (Greenhill et al. 2002; Wilens et al. 2002). Recent studies are aimed at showing superiority of one preparation relative to another, although this approach is not always fruitful; for example, one study comparing various single-dose amphetamine preparations with one another and with placebo over 8 weeks found that they were all superior to placebo; however, immediate-release amphetamines had a faster onset but shorter duration of action; spansules, although much slower to take effect than the others, lasted several hours longer (James et al. 2001).

With respect to individual stimulants, all appear to be equally efficacious in the treatment of ADHD, but they have been reported to have different time courses. In a double-blind, double-control (placebo and methylphenidate) study, the mixed amphetamine salts of Adderall were found to exert their effects rapidly but to dissipate quickly over the course of the day, although Adderall lasted longer than methylphenidate (Swanson et al. 1998). Interestingly, higher doses of Adderall lasted longer than lower doses, indicating a dose-dependent effect in duration of action not found with methylphenidate. Thus, although stimulants may appear to be of equal efficacy overall, there is considerable variability in individual response to each stimulant.

The decision to choose amphetamines or methylphenidate for the treatment of ADHD is often based on the clinician's preference and degree of experience with the medication. At least one important blinded, crossover study found that in performance tasks, both drugs were generally equally efficacious (Efron et al. 1997). Some studies have investigated electroencephalogram (EEG) correlates

that may predict response to methylphenidate or amphetamine. One study comparing good and poor responders to methylphenidate found that those who responded well had higher levels of cortical hypoarousal, showing increases in theta activity and decreases in alpha and beta activity (Clarke et al. 2002b); this is similar to the findings of another group, which suggested that methylphenidate acts by increasing arousal (Loo et al. 1999). With respect to amphetamine, good responders had EEG features more typical of those seen in younger children, indicating that those persons who had a good response to dexamphetamine were more maturationally delayed (Clarke et al. 2002a).

Modafinil is not FDA approved for the treatment of ADHD. A 4-week double-blind study with an 8-week open-label extension found modafinil to be efficacious across all ADHD rating subscales for the duration of the open-label extension (Boellner et al. 2006). Interestingly, 10% of the 220 children studied lost an average of 3 kg, while 4% gained the same. Another such double-blind study found significant efficacy with dosages of 300 mg/day, although heavier children (<30 kg) required 400 mg/day (Biederman et al. 2006). A pooled analysis of three trials (638 patients) found modafinil had similar and impressive improvements in ADHD scales between stimulant-naive and prior-stimulant subgroups, relative to placebo (Wigal et al. 2006). As in other studies, insomnia and headache were the most common, but infrequent, side effects. A 9-week trial (Biederman et al. 2005) found that almost half of patients (mean age 10 years, mean dose 368 mg) were much or very much improved; and efficacy was seen in both inattentive and hyperactive subgroups and both school and home ratings. In this study, weights did not change significantly. Some small but controlled trials (Rugino and Samsock 2003; Turner et al. 2004) found efficacy with modafinil, and in one study (Taylor and Russo 2000) equivalence to dextroamphetamine. However, because of modafinil's apparent low abuse and dependence potential, its use is potentially of interest, but controlled clinical trials are needed to establish any benefit it may have for ADHD. Modafinil is currently indicated only for the treatment of excessive sleepiness associated with narcolepsy, OSAHS, and SWSD.

Stroke and Traumatic Brain Injury

The results from studies on the effects of stimulants in patients who had strokes and traumatic brain injury are mixed. Although small early studies showed some superiority of amphetamine to placebo in improving motor function poststroke (Crisostomo et al. 1988; Walker-Batson et al. 1995), a double-blind study found that 10 mg/day of amphetamine combined with physiotherapy in geriatric stroke patients was not superior to placebo plus physiotherapy in improving activities of daily living or motor function 5 weeks later (Sonde et al. 2001). Neither was amphetamine found to be superior to placebo in improving somatosensory training outcomes (Knecht et al. 2001). In contrast, relative to placebo, dextroamphetamine 10 mg/day significantly improved language recovery in poststroke aphasic patients when immediately coupled with a session of speech therapy; this effect was seen as quickly as within 1 week (Walker-Batson et al. 2001). A recent review lamented the lack of good data in brain-injured patients but did note that available data suggest that the bulk of stimulant efficacy may lie with its improvements in mood and cognitive processing (Whyte et al. 2002).

Although there is a dearth of placebo-controlled studies, there are some interesting reports in which stimulants were compared with antidepressants in patients with poststroke depression. One such study, comparing methylphenidate with TCAs, found similar and significant response to both drugs, although the stimulant worked faster (Lazarus et al. 1994).

Modafinil has been reported to have some therapeutic efficacy in one type of brain injury. Two double-blind studies by the same group (Saletu et al. 1990, 1993) found modafinil effective in improving cognition and accelerating improvement in patients with alcoholic brain syndrome.

The very limited available evidence for the efficacy of certain psychostimulants and modafinil in functional recovery from certain types of brain injury is promising, but much more work needs to be done in this area.

Cocaine and Stimulant Abuse Treatment

It may not be surprising that a double-blind study showed sustained-release dextroamphetamine to be superior to placebo in reducing cocaine use (Grabowski et al. 2001). However, a similarly designed study by the same authors did not find this effect with methylphenidate (Grabowski et al. 1997) (or risperidone [Grabowski et al. 2000]). The implications of this are not obvious. It may suggest that methylphenidate is not as addictive or reinforcing as either cocaine or amphetamine and thus cannot substitute for either of them. This could be because of the slower clearance of methylphenidate from the brain relative to cocaine (Volkow et al. 1995) or, more likely, because the rate at which methylphenidate blocks the DAT is slower than the rate that cocaine blocks it and thus the same subjective "high" is not produced (Volkow et al. 1999). On the other hand, a small open trial found that methylphenidate was effective in cocaine abusers with comorbid ADHD (Levin et al. 1998), suggesting that such individuals may be "self-medicating" with cocaine. A double- blind, placebo-controlled study found that modafinil did not increase the euphoria or craving for cocaine; it may, in fact, have blunted the euphoria (Dackis et al. 2003). A more recent double-blind, placebo-controlled study of 62 patients found that modafinil-treated patients had a longer duration of cocaine abstinence (>3 weeks), with no dropouts due to adverse events (Dackis et al. 2005). Most recently, a 48-day double-blind trial found that under controlled laboratory conditions, modafinil significantly attenuated self-administration and effects of cocaine (Hart et al. 2008). These preliminary investigations suggest that further exploration of modafinil's utility in cocaine abuse treatment is warranted.

Alcohol Dependence

Basic research suggests that amphetamine appears to have an unexpected effect in alcohol abuse disorders. In rats, amphetamines reduced alcohol consumption during choice trials; this reduction was specific to alcohol intake, because amphetamine administration had no effect on rodents' intake of water (Yu et al. 1997). This effect of amphetamine on alcohol consumption may involve the neurobiology of reward systems. Much more research is needed to identify the mechanisms by which stimulants affect alcohol intake.

Narcolepsy

Stimulants have traditionally been used for the treatment of excessive sleepiness associated with narcolepsy. Narcolepsy is characterized by excessive sleepiness that is typically associated with cataplexy and other REM sleep phenomena such as sleep paralysis and hypnagogic hallucinations. Modafinil's approval for treatment of excessive sleepiness in narcolepsy was based on substantial evidence from large multicenter clinical trials (Broughton et al. 1997; U.S. Modafinil in Narcolepsy Multicenter Study Group 1998, 2000). Modafinil is less disruptive of sleep than amphetamines and is rated as having a lower abuse potential (Shelton et al. 1995) (see Table 43–1). A recent study found that taking an extra dose (200 mg) at midday improved wakefulness in patients with narcolepsy without causing insomnia at night (J. R. Schwartz et al. 2004). Importantly, cataplexy—the sudden occurrence of muscle weakness in association with experiencing laughter, anger, or surprise—is responsive to amphetamines but not to modafinil (Shelton et al. 1995).

Fatigue

The use of stimulants for the treatment of fatigue syndromes may seem intuitive, but evidence from large-scale controlled clinical trials to warrant this use is scant. In one of the only double-blind, placebo-controlled studies, men with HIV, depression, and fatigue had significantly less fatigue with dextroamphetamine (73% response) (Wagner and Rabkin 2000). Tolerance, dependence, and abuse were not observed even through a 6-month open phase. A double-blind study of methylphenidate and pemoline in a similar group of 144 patients with HIV who had severe fatigue found both stimulants effective in improving fatigue and quality of life (Breitbart et al. 2001).

Two controlled trials (Adler et al. 2003; Hogl et al. 2002) found modafinil effective in reducing excessive sleepiness in Parkinson's disease. Open-label studies of modafinil for fatigue in multiple sclerosis (Rammohan et al. 2002) and myotonic dystrophy (Damian et al. 2001) are suggestive of modafinil's utility in management of fatigue. A small double-blind crossover study in myotonic dystrophy found reduction in fatigue but no improvement in activity measures (Wintzen et al. 2007). This would be consistent with modafinil's rather selective effect on wakefulness and minimal impact on motor or autonomic parameters. In the same vein, a study of 98 patients with fibromyalgia found that low doses of modafinil (mean 160 mg) substantially reduced fatigue (T. L. Schwartz et al. 2007).

Obstructive Sleep Apnea

There are two placebo-controlled studies of modafinil in the treatment of residual sleepiness in patients with obstructive sleep apnea (OSA) (Kingshott et al. 2001; Pack et al. 2001). The studies show modafinil's efficacy in treating the residual daytime sleepiness experienced by some OSA patients who were compliant in their use of CPAP treatment.

Importantly, modafinil's use was studied in—and should be limited to—the treatment of OSA only after CPAP has been instigated and maximized. OSA carries significant cardiovascular risks if the airway collapse during sleep is not treated appropriately with CPAP and related therapies. It is conceivable that lessened daytime sleepiness from use of modafinil might fool the patient into thinking that CPAP is unnecessary, thus posing a risk via the untreated underlying OSA disorder.
